ABSTRACT

Revealing biodiversity in microbial communities is essential in metagenomics researches. With thousands of sequenced 16S rRNA gene available, and advancements in oligonucleotide microarray technology, the detection of microorganisms in microbial communities consisting of hundreds of species may be possible. Many of the existing strategies developed for oligonucleotide probe design are dependent on the result of global multiple sequences alignment, which is a time-consuming task. We present a novel program named OligoSampling that uses MCMC method to design group-specific oligonucleotide probes. The probes generated by OligoSampling are group specific with weak cross-hybridization potentials. Furthermore a high coverage of target sequences can be obtained. Our method does not need to globally align target sequences. Locally aligning target sequences iteratively based on a Gibbs sampling strategy has the same effect as globally aligning sequences in the process of seeking group-specific probes. OligoSampling provides more flexibility and speed than other software programs based on global multiple sequences alignment.

Keywords: 16S Rrna; Probe Design; MCMC

1. INTRODUCTION

Metagenomics is a new field combining molecular biology and genetics in an attempt to reveal the vast scope of biodiversity in a wide range of environment, as well as new functional capacities of individual cells and communities, and the complex evolutionary relationships between them [1,2,3,4]. Apparently, revealing biodiversity in microbial communities is the first step [1,5]. The

vast majority of microbial diversity had been missed by cultivation-based methods [2]. The analysis of 16S rRNA gene sequences is the most common approach to determine microbial diversity [6].

Oligonucleotide microarrays now afford an idea tool for identifying sequence variants (even single-base-pair variant) in 16S rRNA gene copies of diverse microorganisms simultaneously in a single assay [7,8,9,10]. Many 16S rRNA-based oligonucleotide microarrays have been designed to detect multiple pathogens simultaneously [11, 12.13.14.15]. Such technology has the potential to revolutionize clinical diagnostics [15,16,17,18,19,20,21,22,23].

A critical issue for oligonucleotide microarray design is to find appropriate oligonucleotide probes specific to their target sequences. To improve efficiency in probe design, many softwares or databases have been developed. Kaderali et al. proposed a combination of suffix trees and dynamic programming based alignment algorithms to compute melting temperature (T_m) , and presented an efficient algorithm to select probes with high specificity in detecting the target [24]. Loy et al. built a comprehensive database containing more than 700 published rRNA-targeted oligonucleotide probe sequences with supporting bibliographic and biological annotation [25]. Kumar et al. provided a software package ARB to evaluate sequence alignments and oligonucleotide probes with respect to three-dimensional structure of ribosomal RNA [26]. DeSantis et al. proposed an alignment compression algorithm, NAST (Nearest Alignment Space Termination), to find Operational Taxonomic Units (OTUs) for automated design of effective probes [27,28].

Global multiple sequences alignment plays an important role in comprehensive analysis of group-specific oligonucleotide probe for those methods mentioned above. It is a challenge for personal computer to align a large amount of sequences. Here we present a novel program named OligoSampling that uses MCMC method to design group-specific oligonucleotide probes. OligoSampling does not need to globally align target sequences. This MCMC method is more flexible and efficient.

2. RESULTS

2.1. Algorithm Overview

Figure 1 summarizes the global overview of the Oligo-Sampling algorithm. We assume that we are given a set of *N* sequences $\mathbf{S} = \{S_1, \dots, S_N\}$ and that those *N* sequences are divided into *m* group. We seek a group-specific oligonucleotide probe for each group. For a particular probe of specified width *W* segments in probe binding sites within each sequence are mutually similar. Conversely we seek within each sequence mutually similar segments. The segments can be regarded as

binding sites for a particular probe. If the probe is specific to group **A**, segments within sequences in group **A** are more mutually similar. And to avoid cross-hybridization, there need to be more sequence variants between segments within sequences of group **A** and segments within sequences in any other group. In the process seeking mutually similar segments, patterns shared by multiple sequences in each group are obtained.

The algorithm maintains an evolving data structures. The data structure is a set of positions a_k , for k from 1 to N. For a particular set of positions a_k we obtain the pattern descriptions of mutually similar segments in each group *i* from 1 to *m*, in the form of a probabilistic model of base pair frequencies for each position *j* from 1 to W, and consisting of the variables $q_{i,j,1}, \dots, q_{i,j,4}$.

Figure 1. Algorithm overview: The algorithm is initialized by choosing starting positions a_k , for k from 1 to N, within the various sequences. A Gibbs sampling-based local multiple alignment algorithm [29] is applied to update a_k . After an identical jump for each position a_k , the Gibbs sampling-based local multiple alignment algorithm [29] is applied again to update a_k . An objective function defined to evaluate sensitivity and specificity of probes is calculated based on positions a_k before jump and after alignment respectively. The ratio of objective values is compared to a random number θ uniformly distributed in [0, 1]. The result of comparison determine whether the update of a_k are rejected or not. Then go back to step 1 and start a new iteration loop.

In the process of seeking group-specific probe for group i the algorithm is initialized by choosing starting positions $a_k^{(0)}$ within the various sequences. A Gibbs sampling-based local multiple alignment algorithm [29] is applied to update $a_k^{(0)}$ to $a_k^{(1)}$. After alignment the algorithm then proceeds through many iterations to exe-

cute the following three steps: 1) Jump step. Draw a sample d from a normal distribution. Positions $a_k^{(1)}$ are updated to $a_k^{(2)} = a_k^{(1)} + d$.

2) Local multiple alignment step. Gibbs samplingbased local multiple alignment algorithm is applied re-

$$F(i) = -\sum_{j=1}^{W} \sum_{k=1}^{4} \omega_{j} q_{i,j,k} \log(q_{i,j,k}) + \min_{\substack{1 \le \alpha \le m \\ \alpha \neq i}} \sum_{j=1}^{W} \sum_{k=1}^{4} \omega_{j} q_{\alpha,j,k} \log\left(\frac{q_{\alpha,j,k}}{q_{i,j,k}}\right)$$
(1)

In the objective function sensitivity of the probe is measured by entropy, and specificity is measured by Kullback-Leibler divergence. By selecting a set of a_{i} that maximizes the objective function, the algorithm finds the most group-specific oligonucleotide probe for group *i*.

2.2. Design Group-Specific Oligonucleotide **Probes for 5 Bacterial Species**

To examine the performance of OligoSampling on group-specific probe design, we select 5 bacteria species (Afipia sp., Bordetella pertussis, Brucella sp., Escherichia coli O157:H7, and Mycobacterium tuberculosis) with a total of 40 sequences. For OligoSampling, the input dataset is 5 clusters of homologous sequences. The objective of this algorithm is to find a group-specific oligonucleotide probe for each cluster. As shown in Figure 2, the probes generated by OligoSampling are group specific with weak cross-hybridization potentials. Oligo-Sampling also obtains a high coverage of target sequences.

3. DISCUSSION

The secondary structure model of 16S rRNA consists of a conserved core that is interspersed with a number of variable areas. 16S rRNA evolves slowly and is often not very convenient to resolve bacterial strains at the species level. Therefore, multiple copies of 16S rRNA gene in different species share high sequence similarity. In jump step each aligned position a_k is updated by jumping a same distance in the same direction. Convergence will be achieved rapidly in the following alignment due to high sequence similarity between sequences (Figure 3). In the process of updating positions a_k , Gibbs sampling-based local multiple alignment algorithm is applied to keep sequences locally aligned. And then, sensitivity and specificity of probe is evaluated based on entropy and Kullback-Leibler divergence. This process is functionally equivalent to oligonucleotide probe design based on global multiple sequences alignment, but has

garding positions $a_k^{(2)}$ as initial starting point. Positions $a_{k}^{(2)}$ are updated to $a_{k}^{(3)}$.

Rejection step. We define an objective function (Eq.1). Based on positions $a_{i}^{(1)}$ and $a_{i}^{(3)}$, the objective function $F_{previous}(i)$ and $F_{next}(i)$ are calculated respectively. We generate a random number θ uniformly distributed in [0, 1]. If $\theta \leq F_{next}(i)/F_{previous}(i)$, we accept $a_k^{(3)}$. Otherwise, positions resume to $a_{\mu}^{(1)}$. Then, go back to step 1.

$$(i) = -\sum_{j=1}^{W} \sum_{k=1}^{4} \omega_j q_{i,j,k} \log\left(q_{i,j,k}\right) + \min_{\substack{1 \le \alpha \le m \\ \alpha \ne i}} \sum_{j=1}^{W} \sum_{k=1}^{4} \omega_j q_{\alpha,j,k} \log\left(\frac{q_{\alpha,j,k}}{q_{i,j,k}}\right)$$
(1)

less calculation amount.

Through the iterative algorithm mentioned above, different initializations sometimes lead to different local optimal solutions. Therefore, searches beginning with multiple initializations have more possibility to achieve global optimal solution. Searches beginning with different initializations are mutually independent and can be executed in parallel. It is convenient to parallelize this algorithm.

Gibbs sampling-based local multiple alignment algorithm is sensitive to starting positions a_{i} . Appropriate starting positions a_k can quicken convergence speed.

Figure 3. Convergence of local alignment: Optimal objective values converge in 10000 iterations under three conditions: after jump, beginning with starting positions proportional to sequence length, and beginning with random starting positions. To make the comparison of convergence speed independent of initialization, ten alignment procedures beginning with different sets of starting positions are executed under each condition. Average optimal objective values in iterations 1 to 10000 were normalized to that in last iteration.

Sets of target sequences are highly similar to each other. We choose initial starting positions by letting the distance from 5' termini to initial starting position in each target sequence be proportional to sequence length. As shown in **Figure 3**, Local alignment beginning with proportional starting positions can achieve faster convergence speed than that beginning with random starting positions. In this method, the algorithm is initialized by choosing a random proportion. And the proportion is used to find starting position in each target sequence.

It is noted that if a probe can match well with several segments in a 16S rRNA, local multiple alignment can not analyze this situation comprehensively. We have analyzed the possibility that a probe matches well with several segments in a 16S rRNA. At present, the Ribosomal Database Project [30] (RDP) has collected around 280,952 16S rRNA sequences in bacteria superkingdom. Among the 280,952 16S rRNA sequences we picked out a 16S rRNA sequence and chose a segment in this 16S rRNA randomly. And then in this 16S rRNA sequence another segment which is most similar to the original segment was found. Mismatches of the two segments were counted. The procedure mentioned above was iterated 10,000 times. As shown in Figure 4, there is little possibility that a probe can match well with several segments in a 16S rRNA.

The problem of group-specific probe selection is further complicated as all probes must work under the same hybridization condition. To ensure the closer optimum

Figure 4. Mismatch in similar segments: Among 280,952 16S rRNA sequences in bacteria superkingdom collected by RDP, we picked out a 16S rRNA sequence and chose a segment in this 16S rRNA randomly. And then in this 16S rRNA sequence another segment which is most similar to the original segment was found. Mismatches of the two segments were counted. The procedure mentioned above was iterated 100,000 times.

hybridization condition in one chip including all oligos, probe lengths must be variable. By adjusting probe lengths (increase or decrease base-pairs in 5' and 3' ends), probe whose melting temperatures (T_m) are closer to a predefined optimum hybridization condition will be generated. As shown in **Table 1**, probe lengths are selected based on a predefined melting temperature. Melting temperatures of all probes can be close enough to work well under the same hybridization condition.

4. CONCLUSIONS

OligoSampling provides an efficient alternative for group-specific oligonucleotide probe design. Using this method we do not need to globally align target sequences. Locally aligning target sequences iteratively based on a Gibbs sampling strategy has the same effect as globally aligning sequences in the process of seeking group-specific probes. OligoSampling provides more flexibility and speed than other software programs based on global multiple sequences alignment. Furthermore, search for multiple local optimal solutions beginning with multiple initializations can improve the effect of this algorithm in group-specific probe design. This algorithm can be parallelized conveniently.

5. METHODS

5.1. A Gibbs Sampling Strategy for Local Multiple Alignment

Lawrence *et al.* have described a Gibbs sampling algorithm for local multiple alignment of protein sequences [29]. We applied Lawrence's method to locally align target sequences.

Pattern shared by multiple sequences is described in the form of a probabilistic model of base pair frequencies for each position *i* from 1 to *W*, and consisting of the variables $q_{i,1}, \dots, q_{i,4}$. This pattern description is accompanied by an analogous probabilistic description of the "background frequencies" p_1, \dots, p_4 with which base pairs occur in sites not described by the pattern.

Through many iterations to execute two steps of the Gibbs sampler an objective function (**Eq.2**) evaluating the alignment is maximized. In the study, the two steps of the Gibbs sampler were executed to locally align target sequences.

$$F = \sum_{i=1}^{w} \sum_{j=1}^{4} c_{i,j} \log \frac{q_{i,j}}{p_{j}}$$
(2)

First step, one of the *N* sequences, z, is chosen in specified order. The pattern description $q_{i,j}$ and background frequencies p_j are calculated, as described in **Eq.3**, from the current positions a_k in all sequences excluding z.

Table 1. Adjust probe lengths according to a predefined optimum hybridization condition (70 $^{\circ}$ C).

Original probe	iginal probe T_m Adjusted probe		T_m
3'-GTTGGGGGCCTTGACGGAAAC-5'	74.98	3'-GGGGCCTTGACGGA-5'	71.07
3'-AACCCCGGAAGCCCGGAACC-5'	80.38	3'-CCGGAAGCCCGGA-5'	70.93
3'-CTTGTTGTGTCCCTTTGAAC-5'	66.40	3'-CCTTGTTGTGTCCCTTTGAAC-5'	70.05
3'-CCGAAGGCCTCGATTGCGCA-5'	78.59	3'-GAAGGCCTCGATTGCGC-5'	70.69
3'-ACAACCACCCCACTGCCGGA-5'	82.37	3'-ACCACCCCACTGCCG-5'	71.66

$$q_{i,j} = \frac{c_{i,j} + b_j}{N - 1 + B}$$
(3)

For the *i*th position of the pattern we have N-1 observed nucleotides, because sequence *z* has been excluded; let $c_{i,j}$ be the count of nucleotide *j* in this position. These $c_{i,j}$ are supplemented with nucleotide-dependent "pseudocounts" b_j to yield pattern probabilities. *B* is the sum of the b_j .

Second step, the probability Q_x of generating segment x in position a_z according to the current pattern description $q_{i,j}$ are calculated, as are the probability P_x of generating this segment by the background probabilities p_j . The weight $A_x = Q_x/P_x$ is assigned to current segment x. And then draw a sample d from a normal distribution. Positions a_z are updated to $a_z + d$. In the updated position weight A'_x is calculated in the same way. We generate a random number θ uniformly distributed in [0, 1]. If $\theta \leq A'_x/A_x$, we accept the update of positions a_z . Otherwise, we reject the update. Then go back to first step.

5.2. Selection of Weight Set in Sensitivity and Specificity Evaluation

Pozhitkov *et al.* examined the effects of single-base pair mismatch (all possible types and positions) on signal intensities of hybridization through a series of calibration experiments [31]. The results of experiments indicated that the most optimal discrimination of mismatch from perfect match probe-target duplexes is provided with the mismatch in the middle of the duplex. To suppress non-specific binding of probe to target, the position of the mismatch should be moved from the 5' or 3' termini to the center of the probe. Therefore, in evaluation of sensitivity and specificity of group-specific oligonucleotide probes the weight coefficients ω_i (in

Eq.1) should dependent on the signal intensity values of mismatches in different positions. Based on normalized signal intensity values of mismatch duplexes at position

1 to 20 provided by Pozhitkov *et al.*, the weight coefficients ω_j are assigned. Position in the middle has the highest weight.

3. ACKNOWLEDGEMENTS

This work was supported by a grant from the National Natural Science Foundation of China (No. 30800253). The authors thank anonymous referees and the associate editor for many helpful comments.
