Abstract

It’s quite difficult to diagnose the meniscus tear by clinical examination even the experienced orthopaedic surgeon, so this review has shortly focused on clinical examination and its treatment. How to overcome missed diagnosis of meniscus tear in clinical setting? This review article highlighted the importance of early diagnosis and treatment; fortunately, these processes have been vastly improved by advances in Magnetic resonance imaging (MRI) and Arthroscopy. Although partial, subtotal and total meniscectomy is the choice for different types of meniscal tears, there are certain criteria to be meet for undergoing surgical treatment. The most common criteria for meniscal repair include: 1) A vertical longitudinal tear more than 1 cm in length located within vascular zone, 2) A tear which is unstable and displaceable into the joint, 3) An active informed and cooperative patient but younger than 40 years old, 4) A stable knee or wound stabilized with a ligamentous reconstruction. Chronically deformed or degenerative menisci are bottom-out candidates for repair. Most investigators report that only 10% to 15% of meniscal tears can be repaired and that most such repairs are done in association with an anterior cruciate ligament reconstruction. However, this article presents a review of the clinical relevant anatomic, function, repair and healing mechanism, description of the meniscus attachment as well as current strategies for accurate diagnosis and treatment of common injuries to these meniscus attachments.

1. Introduction

Meniscal function is essential to the normal function of the knee joint. For the
menisci to function properly, the biomechanical integrity of each meniscus root on the tibial plateau must be maintained [1] [2]. Various functions have been attributed to the menisci, some of which are known or proved and others that are theorized. The menisci act as joint filler, compensating for gross incongruity between femoral and tibial articulating surface. So located, the menisci prevent capsular and synovial impingement during flexion-extension movements. The menisci have been believed to have a joint lubrication function, helping to distribute synovial fluid throughout the joint and aiding the nutrition of the articular cartilage [3] [4] [5] [6]. They undoubtedly contribute to stability in all planes but are especially important rotary stabilizers and are probably essential for the smooth transition from a pure hinge to a gliding or rotary motion as the knee moves from flexion to extension. The menisci are crescents, roughly triangular in cross-section, that cover one half to two-thirds of the articular surface of the corresponding tibial plateau [7] [8] [9]. They are composed of dense, tightly woven collagen fibres arranged in a pattern providing great elasticity and ability to withstand compression. The major orientation of collagen fibres in the meniscus is circumferential, radial fibres and perforating fibres determines to some extent the characteristic pattern of meniscal tears. When meniscal samples are tested by application of a force perpendicular to the fibre direction, the strength is decreased to less than 10% because collagen fibres function primarily to resist tensile force along the direction of the fibres. The circumferential fibres act much in the same way as metal hoops are placed around a pressurized wooden barrel [3] [4] [6].

The peripheral edges of menisci are convex [3] [10], fixed and attached to the inner surface of the knee joint capsule, except where the popliteus is interposed laterally; these peripheral edges also are attached loosely to the borders of the tibial plateaus by the coronary ligaments. The inner edges are concave, thin and unattached. The menisci are largely a vascular except near their peripheral attachment to the coronary ligament. The inferior surface of each meniscus is flat, contour of the underlying tibial plateau and superimposed femoral condyle. The \textit{medial meniscus} is a C-shaped structure larger in radius than the lateral meniscus, with the posterior horn being wider than the anterior. The anterior horn is attached firmly to the tibia anterior to the intercondylar eminence and to the anterior cruciate ligament. Berlet and Flower also described the anterior horn as associating with the ACL in 59% of knees. Other researchers have reported the anterior horn as connecting to the anterior intermeniscal ligament, also known as transverse ligament, in approximately 70% of knees [8] [11] [12] [13]. Most of the weight is borne on the posterior portion of the meniscus. The posterior horn is anchored immediately in front of the attachments of the eminence. Its entire peripheral border is firmly attached to the medial capsule and through the coronary ligament to the upper border as the tibia. The \textit{Lateral meniscus} is smaller in diameter, thicker in periphery, wider in body, and more than the medial meniscus. It is attached to both cruciate ligaments and posteriorly to the medial femoral condyle by either the ligament of Humphry or the ligament of Wrisberg, de-
pending on which is present; it is also attached posteriorly to the popliteus muscles. It is separated from the lateral collateral ligament by the popliteal tendon. In contrast, the medial meniscus is much larger in diameter, is thinner in its periphery and narrower in body, and does not attached to either cruciate ligament. It is loosely attached to the medial capsular ligaments. Zantop reported that anteromedial bundle of the ACL was an average of 5.2 mm medial and 2.7 mm posterior to the lateral anterior root, while the poster lateral bundle was an average 11.2 mm posterior and 4.1 mm medial to the anterior root [14]. Ziergler reported that centre of ACL was on average 7.5 mm medial to the anterior root of the lateral meniscus centre, 8.5 mm anteromedial to the poster medial aspect of the anterior horn of the lateral meniscus and 10.2 poster medial to the anteromedial aspect of the anterior horn [15]. The vascular supply to the medial and lateral menisci originates predominantly from the lateral and medial geniculate vessels (both inferior and superior). Branches from these vessels give rise to a perimeniscal capillary plexus within the synovial and capsular tissue.

2. Meniscal Healing and Repair

The vascular supply to the meniscus determines its potential for repair. The peripheral meniscal blood supply is capable of producing a reparative response similar to that observed in other connective tissues because of a perimeniscal capillary plexus that supplies the peripheral 10% to 25% of the menisci. Meniscal tears have been classified based on their location in three zones of vascularity

1) Red (fully within the vascular area).
2) Red-white (at the border of the vascular area).
3) White (within the avascular area).

This classification indicates the potential for healing after repair and section on surgical repair of torn menisci. After injury within the peripheral vascular zone, a fibrin clot that is rich in inflammatory cells forms. The healing process depend on debriment or abrasion of wall of the tear, especially in chronic lesion [16]. Vessels from the peri-meniscal capillary plexus proliferate throughout this fibrin scaffold and are accompanied by the proliferations of differentiated mesenchymal cells. The lesion is eventually filled with cellular fibro vascular scar tissue that glues the wound edges together and appears continuous with the adjacent normal meniscal fibro cartilage. Vessels from the peri-meniscal capillary plexus as well as the proliferative vascular pannus from the synovial fringe penetrate the fibrous scar to provide a marked inflammatory response. Although several months are required for maturation to fibro cartilage that appears normal.

3. Tears of Menisci

A rotational force incurred while the joint is partially flexed usually tears a meniscus. During vigorous internal rotation of the femur on the tibia with the knee flexion, the femur tends to force the medial meniscus posteriorly and toward the centre of the joint. A strong peripheral attachment posteriorly may prevent the
meniscus from being injured, but if this attachment stretches or tears, the posterior part of the meniscus is forced toward the centre of the joint, is caught between the femur and the tibia, and is torn longitudinally when the joint is suddenly extended. If this longitudinal tear extends anteriorly beyond the medial collateral ligament, the inner segment of the meniscus is caught in the intercondylar notch and cannot to its former position: thus, a classic bucket-handle tear with locking of the joint is produced. The same mechanism can produce a posterior peripheral or a longitudinal tear of the lateral meniscus; the lateral femoral condyle forces the anterior half of the meniscus anteriorly and toward the centre of the joint, and this strain in turn may tear the posterior half of the meniscus from its peripheral attachment. When the joint is extended, a longitudinal tear results. Because it not as susceptible to bucket-handle tears; however, because it is more sharply curved and is neither attached to nor controlled by the lateral collateral ligament, the lateral meniscus sustains incomplete transverse tears more often than does the medial meniscus.

4. Classification

Numerous classifications of tears of the menisci have been proposed on the basis of location or type of tear, etiology and other factors; most of the commonly used classification are based on the type of tear found at surgery:

1) Longitudinal tears.
2) Transverse and oblique tears.
3) Combination of longitudinal and transverse tears.
4) Tears associated with cystic menisci.
5) Tears associated with discoid menisci.

The most common type of tear is longitudinal tear, usually involving the posterior segment of either the medial or the lateral meniscus, before the extensive use of arthroscopy for diagnosis and treatment of meniscal injuries, tears of the medial meniscus in most series were approximately five to seven times more common than those of the lateral meniscus. However, increase in use of the arthroscopy, allow better inspection of both menisci, more lateral meniscal tears have been diagnosed. Small tears limited to the posterior horn are not capable of producing locking but will cause pain, recurrent swelling and a feeling of instability in the joint. Extensive longitudinal tear can cause mechanical locking if the central portion of the meniscus is displaced into the intercondylar notch. A pedunculated fragment may result if either the posterior or the anterior attachment of the bucket-handle fragment becomes detached. Transverse, radial or oblique tears can occur in either meniscus but more commonly involve the lateral meniscus. Because the lateral meniscus is more of a circle and has a shorter radius, the inner free edge transversely torn more easily than its medial counter-part. Transverse tears also can result from degenerative change within the meniscus itself or from injury or conditions such as cystic changes at the periphery that render the meniscus less mobile. Cysts of menisci are frequently associated with tears and are nine times more common on the lateral than on the medial side.
The most common cause is trauma that produces degeneration and secondary mucinous and cystic changes follow, the meniscus may become less mobile during flexion, extension and rotary motions and thus more susceptible to additional longitudinal or transverse tearing. Discoid menisci are abnormal and because of hyperactive mobility and the bulk of the tissue between the articular surfaces, they are vulnerable to compression and rotary stresses, may develop degeneration within the discoid meniscus, as well as tear. The diagnosis often is not produce significant symptoms unit some derangement of the meniscus occurs.

5. Diagnosis

The diagnosis of a meniscal tear can be difficult even for an experienced orthopaedic surgeon. Use of a careful history and physical examination and supplementation of standard radiographs in specific instances with special imaging techniques and arthroscopy can keep errors in diagnosis of tears of the menisci to less than 5%. When a meniscus has been injured, capsular and ligamentous structures as well as the articular surfaces also often have been injured. The syndrome caused by tears of the menisci can be divided into two group; those in which there is locking and the diagnosis is more difficult. If a patient does not have locking, the diagnosis of a torn meniscus is more difficult even for the most astute surgeon. A patient typically gives a history of several episodes of trouble referable to the knee, often resulting in effusion and a brief period of disability but no definite locking. A sensation of “giving way” or snaps, clicks, catches, jerks in the knee may be described, or the history may be even more indefinite, with recurrent episodes of pain and mild effusion in the knee and tender seen in the anterior joint space after excessive activity. When they are well understood, the following clues can be important in the differential diagnosis in this second group: a sensation of giving way, effusion, atrophy of the quadriceps, tenderness over the joint line (or the meniscus during the physical examination).

A Sensation of giving way is in itself of little help in diagnosis because it can occur in other disturbances of the knee, especially loose bodies, chondromalacia of the patella and instability of the joint resulting from injury to the ligaments or from weakness of the supporting musculature, especially the quadriceps. When this symptom results from a tear in the posterior part of a meniscus, the patient usually notices this on rotary movements of the knee and often associates it with a feeling of subluxation or “the joint jumping out of place”. When giving way is a result of other cause, such as quadriceps weakness, it usually is noticeable during simple flexion of the knee against resistance, such as in walking down stairs.

6. Diagnostic Clinical Tests

6.1. The McMurray Test

With the patient supine and the knee acutely and forcibly flexed, the examiner can check the medial meniscus by palpating the poster medial margin of the
joint with one hand while grasping the foot with the other hand. Keeping the knee completely flexed, the leg is externally rotated to the maximum extent and then the knee is slowly extended. As the femur passes over a tear in the meniscus, a click may be heard or felt. The lateral meniscus is checked by palpating the posterolateral margin of the joint, internally rotating the leg as far as possible and slowly extending the knee while listening and feeling for a click. A click produced by the McMurray test is usually caused by a posterior peripheral tear of the meniscus and occurs between complete flexion of the knee to 90 degrees. Popping, which occurs with greater degrees of extension when it is definitely localized to the joint line, suggests a tear of the middle and anterior portions of the meniscus. The position of the knee when the clicks occur thus may help locate the lesion. A McMurray click localized to the joint line is additional evidence that the meniscus is torn; a negative result of the McMurray test does not rule out a tear. McMurray testing was positive in only 57.1% of patient and effusion was noted in only 14.3% [17].

6.2. The Grinding Test

With the patient prone, the knee is flexed to 90 degrees and the anterior thigh is fixed against the examining table. The foot and leg are pulled upward to distract the joint and rotated to place rotational strain on the ligaments; When ligaments have been torn, this part of the test usually is painful. Next, with the knee in the same position, the foot and legs are pressed downward and rotated as the joint is slowly flexed and extended, when meniscus has been torn, popping and pain localized to the joint line may be noted. Although the McMurray, Apleys and other tests cannot be considered diagnostic, they are useful enough to be included in the routine examination of the knee.

6.3. The Squat Test

Several repetitions of a full squat with the feet and legs alternately fully internally and externally rotated as the squat is performed. Pain usually is produced on either the medial or the lateral side of the knee, corresponding to the side of the torn meniscus. Pain in the internally rotated position suggest injury to the lateral meniscus, whereas pain in the external rotation suggests injury to the medial joint line or the lateral joint line, however, is a much more dependable localizing sign than the position of rotation.

6.4. The Thessaly Test

The examiner supports the patient by holding his or her outstretched hands while the patient stands flatfooted on the floor. The patient then rotates his or her knee and body, internally and externally, three times with the knee in slight flexion (5 degrees). The same procedure is carried out with the knee flexed 20 degrees. Patients with suspected meniscal tears experience medial or lateral joint-line discomfort and may have a sense of looking or catching. The test is
always done on the normal knee first to teach the patient how to keep the knee in 5 and 20 degrees of flexion and how to recognize a possible positive result in the symptomatic knee. The Thessaly test at 20 degrees of knee flexion was suggested to be effective as a first-line clinical screening test for meniscal tears.

7. Imaging

With the improvements in CT [18] and MRI scanning [19], have been shown to improve diagnostic accuracy in many knee disorder. MRI scanning is first choice for diagnosis of meniscus tear rarely use of arthrograph.

A root tear could be demonstrated on pre-operative M.R.I in only 72.9% of the patient, while the rest demonstrated degeneration and/or fluid accumulation at the posterior horn without a visible meniscal tear [20]. Other, have reported significantly improved detection ability up to 93.3% sensitivity, 100% specificity and 100% positive predictive value using a variety of magnetic resonance sequences and interpretation signs suggestive of root tears [21] [22] [23]. The detailed for Meniscus tear and its management has been discussed in Figure 1 with a flowchart.

8. Management of Meniscus Tear

8.1. Non-Operative Management

If the knee is locked, it is manipulated under general anaesthesia. No special manoeuvre is needed. As the knee relaxes, the torn meniscus falls into place and knee is unlocked. The knee is immobilised in a Robert-Jones compression bandage for 2 - 3 weeks, followed by physiotherapy. In a case where locking is not present, Immobilisation with the Robert-Jones bandage is sufficient. With this, a small number of peripheral tear will heal. Rest of the tears may produce recurrent symptoms. Consists of a groin-to-ankle cylinder cast or knee immobilizer worn for 4 to 6 weeks. Crutch walking with touch-down weight bearing is permitted when the patient gains active control of the extremity in the cast. The patient is instructed in a progressive isometric exercise program during the time the legs is in the cast to strengthen the quadriceps, the hamstrings and the gastrocnemius and soleus muscles around the knee as well as the flexors, abductors, adductors and extensors around the hip. At 4 to 6 weeks, the immobilization is discontinued and the rehabilitative exercise program for the muscles around the hip and knee is intensified.

• **Knee braces (Knee immobilizer):** In most cases, the injury can heal within months. Surgery is rarely required only in most severe cases. Aside from surgery, less invasive treatments can help as well, including rest, ice, pain relievers and physical therapy. After a meniscus tear, patients are also going to start researching quality knee braces. Knee braces may help to recover from a torn meniscus injury and prevent aggravating and existing condition [24]. Let’s delve into how a knee brace can help you recover from a torn meniscus.
Knee injury/pain by twisting movement with a flexed knee.

Clinical presentation:
- Recurrent episode of pain and locking of the knee.
- Sudden jerk while walking (Something flicking over inside the joint).
- May followed by swelling, appearing after a few hour and lasting for few days.
- May be swelling appearing overnight as the effusion collects. After the effusion

Chance to missing diagnosis of meniscal tears by clinical

Locking may be missed because the attention is drawn to more obvious signs of pain and swelling. The displaced fragment sometimes return to its original position spontaneously and thus the original episode of locking may never be noticed.

The history of sudden, locking and unlocking, with a click located in one or other joint compartment, is a diagnostic of meniscal tear.

On Clinical Examination: There are some test, which help in diagnosis for meniscal tear,
- The Mc Murray test.
- The Grinding test.
- The Squat test.
- The Thessaly test

Investigation to be done for diagnosis of meniscal tears

Radiological Examination:
- X-rays: With meniscal tear, there are no abnormal X-ray findings.
- M.R.I: is a non-invasive method of detecting meniscus, main choice of radiological investigation.

Arthrography: It is a technique where X-rays are taken after injecting radiopaque dye into knee. The dye outlines the menisci, so that a tear, if present, can be visualised. Being an invasive technique, it is no longer used.

Arthroscopy: This a technique where a thin endoscope, about 4-5 mm diameter, the arthroscope, is introduced into joint through a small stab wound and inside of joint examined

There is certain criteria to be meet for undergoing surgical treatment, the most common criteria for meniscal repair include
1. A vertical longitudinal tear more than 1 cm in length located within vascular zone,
2. A tear that is unstable and displaceable into the joint,
3. An informed and cooperative patient who is active and younger than 40 years old,
4. Stabilize a knee that either is stable or wound with a ligamentous reconstruction.

If diagnosis of meniscal tear, has been diagnosed earlier and its does not met the criteria, than

Conservative treatment of meniscal tears:
- Ice, rest, elevation of knee.
- NSAIDS and analgesics.
- Robert-Jones compression bandage for 2-3 weeks followed by physiotherapy.
- Knee braces for 4-6 weeks followed by physiotherapy.

If meniscus tear remain undiagnosed then further operative management should be followed as follows

Arthrotomy (Open-up the joint):
The treatment is to excise the displaced meniscus by open-up the joint.

Menisectomy by arthroscopy (minimal invasive):
- three categories depending on the amount of meniscal tissue to be removed,
  1. Partial Menisectomy.
  2. Subtotal Menisectomy.
  3. Total Menisectomy.

Figure 1. Flowchart on Meniscal tears and its management.
Providing stability: Wearing a rehabilitative knee brace will help the patient recover from a torn meniscus by providing stability to the joint and preventing the wearer from aggravating the injury even further, knee braces with hinges on either side of the knee offer protection and prevent that wobbly feeling patient may get after a knee injury.

Preventing hyperextension: A knee brace will prevent the patient from extending the knee beyond their normal range of motion. One of the most common causes of a torn meniscus in hyperextension at the knee.

Increased confidence: Wearing knee brace can help increase patient confidence and give them the push they need to execute their therapy program and get back on the road to recovery.

Pain relief: A well-constructed knee brace will have an unloading effect on the wearer’s knee. The brace reduces the direct pressure from the upper leg on the meniscus, which results in pain relief. When you have less pain, it is more likely that you will be more active and stick to your physical therapy program.

Increased circulation: Knee braces add pressure to the affected area, which encourages greater circulation. Blood flow to the area brings oxygen and fresh nutrients which speed recovery. Research shows that about 30% of the meniscus (the outer portion) has its own blood supply. The rest of the meniscus receives its nutrition from synovial fluid in joint capsules. The nutrients in the synovial fluid diffuse to the meniscus through movement. Keep in mind one of the main benefits of knee braces is that they help you stay active, which is a major part of recovery.

Exercise for meniscus tear and knee injury: The exercises increase in difficulty as pain levels decrease. Initially after the injury, you want the patient to rest, ice and elevate the knee, as well as wear a knee brace to help reduce swelling. Crutches may be advised for weight-bearing activities such as walking. Soon after, depending on the damages, you want the patient to start working a range of motion. Exercise to help prevent further damage and further loss of range of motion. These exercises can be as easy as flexing and extending the knee, within pain-free limits [25]. After the pain continues to decrease and the patient can perform range of motion exercise without pain, the patient can progress to the next stage of the rehabilitation process. The clinician can assist the patient in stretching the hamstrings, quadriceps and iliotibial band to help prevent the surrounding muscles from becoming tight. If the patient remains pain free, than simple exercise can be introduced [26].

Quad sets exercise: With the injured leg fully extended, place a small towel under the back of the knee. Contract the Quadriceps muscles by pushing the knee towards the ground [27].

Short-Arc-Quad-Extensions exercise: Place a towel under the injured knee, so the knee is bent at about 45°, extend the knee and held for about 10 seconds than relax in the resting position.
o **Straight leg raises exercise:** Lying flat on your back, bend your uninjured leg 90°, leaving your injured leg straight. Lift your injured leg about 12 inches off the ground, keeping your thigh muscles contracted and hold for about 5 seconds, then lower the leg slowly back of the ground.

o **Toe raises (with Tubing) exercise:** In a seated position with the injured leg fully extended, injured leg fully extended, tubing can be placed around the top of the foot (Either held by the clinician or tried to a table) and the athlete can perform toe raises with resistance.

o **Lunges exercise:** In a standing position, the patient brings one foot forwards and then bends at the knees keeping the back straight. The knee of the back leg should come close to the ground, and the knee of the front leg should not go past the toes, both legs should form a 90° angle between the thigh and lower leg.

o **Squats exercise:** In a standing position, the patient should spread the feet to be above shoulder width apart. The patient should then bend at knee to form a 90° angle. The knee should not go past the toes, and the patient should make sure to maintain a flat back so as not to strain.

The patient must be informed that any tear in the meniscus may not have healed despite this period of immobilization [28]. If symptoms recur after a period of non-operative treatment, surgical repair or removal of the damaged meniscus may be necessary and more specific diagnostic procedures such as MRI and arthroscopy are used as indicated.

### 8.2. Operative Management by Arthroscopy (Menisectomy)

This is a technique where a thin endoscope, about 4 - 5 mm in diameter—the arthroscopy, is introduced into the joint through a small stab wound and inside of joint examined, repaired.

- **General Principal for Arthroscopy:** Arthroscopy of the knee can be done as the essential initial step before proceeding to operative arthroscopy or before an open arthrotomy. Anaesthesia can be local, regional block, or general. If the procedure is uncomplicated and of short duration, it can be done using local anaesthesia in cooperative patients, especially if the surgeon is experienced in arthroscopy [29]. If local anaesthesia is to be used, we prefer intravenous sedation for portal injection with 1% lidocaine and an intraarticular bolus of 30 ml bupivacaine and 15 ml of lidocaine 20 minutes before starting the procedure. Diagnostic arthroscopy before arthrotomy or major intraarticular surgery anesthesia, unless this type of anaesthesia is contraindicated. The procedure is performed in the operating room under strict sterile conditions. Must not minimized the seriousness of this surgical procedure. Although complications such as infection are infrequent (<1%), carelessness in surgical scrubbing, preparation, or draping or careless handling of the irrigating solutions, arthroscopes, and instruments can result in intraarticular infection just as devastating as those after arthrotomy. Sterilization of arthro-
scopy equipment and use of waterproof arthroscopy gowns and drapes are essential. Sealing the extremity proximal and distal to the arthroscopy site and use of a durable skin preparation (Dura Prep) and iodine-impregnated drape at the surgical site can help to minimize infections.

The scrub nurse uses a large table for instruments. This is positioned for the nurse’s convenience, usually on the same side as the knee having surgery. A Mayo stand is placed over the operating table at the upper part of the patient’s thighs, and the more commonly used instruments are placed on it. Power cords and light cables are attached to the appropriate sources and are placed on a side table. Irrigation bags are suspended from an intravenous stand at the head of the table and are raised 3 to 4 feet above the level of the patient. The use of an arthroscopic pump for inflow through the arthroscope sheath or a separate sheath helps keep flows and pressure constant. The pump may eliminate the need for a tourniquet, making arthroscopy using local anaesthesia feasible. A tourniquet is placed around the thigh but is not inflated in diagnostic arthroscopy unless troublesome bleeding occur, Inflation of the tourniquet blanches the synovium and other vascularised tissues and make diagnostic evaluation of these structures more difficult. Meniscal vascularity and healing potential should be evaluated with the tourniquet deflated and the intraarticular hydrostatic pressure low. The tourniquet usually is inflated after exsanguinations of the limbs in acute traumatic disorders, or if the surgeon anticipates anything other than the simplest intraarticular surgical procedure. Tourniquet time should be minimized and not exceed 90 minutes for routine procedures to prevent possible deep vein thrombosis. For major complicated procedures, tourniquet times of 2 hours can be used, but times longer than this should be avoided to prevent ischemic neurovascular changes. Stressing the knee to open up the various compartments is necessary for diagnostic or operative procedures. This can be accomplished by using an assistant, a padded lateral post, or a commercial leg-holding device. The use of an assistant to stress the joint probably is the least efficient methods because of fatigue and the inconsistent amounts of stress that results, among other factors. The use of a padded lateral post attached to the edge of the operating table can be effective for valgus stressing in or near full extension, but it does not control rotation. The commercial thigh holders are most effective, but some of their potential dangers must be kept in mind. Although the use of leg-holding devices makes stressing and opening the compartments easier, especially the posterior compartment, these devices do get in the way when one is working through the superior portals in the patellofemoral joint. Also, the potential tourniquet effect of the leg-holding devices must be appreciated. In osteoporotic bone, excessive stress can result in fracture to the rigidly held extremity.

Once the diagnosis is established clinically, the treatment is it excise the displaced fragment of the meniscus by opening-up the joint (arthrotomy). Now a day, it is possible to excise a torn meniscus arthroscopically (arthroscopic surgery). By this technique, once the fault is detected e.g. a loose meniscal flap, the same is excised using fine cutting instruments introduced from another punc-
ture wounds. This technique is a significant advance as it can be done as a day care procedure, sometimes even under local anaesthesia. Since it is a minimally invasive technique, early return to work is possible. Recent research has shown that menisci are not “useless” structure as was through earlier. Hence, wherever possible the trend is to preserve the meniscus by suturing (Meniscorrhaphy).

- General principles of meniscal excisions and different categories (Meniscectomy): Partial meniscectomy is always preferable to subtotal or total meniscectomy [30] [31]. Leaving an intact, balanced, peripheral rim of meniscus aids in the stability of joint and protects the articulars surface by its load-bearing function. Total meniscectomy removes all of the actual load-bearing protection and reduces stability of the joint, especially if a concomitant ligamentous relaxation already exists. Partial meniscectomy, although desirable, is not always possible if the tear extends to the periphery of the meniscus [32]. In such cases, subtotal excision is preferable to complete excision, even though the contoured anterior meniscal tissue left may be subject to subsequent tears or degeneration. To determine accurately the type of meniscectomy required, the meniscal lesion must be carefully probed and classified. Failure to classify, probe, and explore accurately and thoroughly the extent and various planes of tear before proceeding with the meniscal resection often results in needlessly sacrificing healthy meniscal tissues. When the meniscal tear has been probed and classified, the surgeon should mentally formulate the methods and steps required to excise the necessary portion of the meniscus. The surgeon should be able to visualize the tissues to be removed and the subsequent contour of the peripheral meniscal rim. The objectives is to remove the torn, mobile meniscal fragment and contour the peripheral rim, leaving a balanced, stable rim of meniscal tissues. Excision of the pathological tissue can be done either with en bloc resection of the mobile fragment or by morcellization of the fragments and subsequent removal. Sharp excision of the major mobile fragments usually is preferable to morcellization to minimize the potential debris within the joint [32]. When the tear has been removed, the remaining peripheral rim must be carefully probed to ensure that there are no additional tears and that the rim is balanced and stable. When a contoured, balanced, stable peripheral rim is present, the joint should be thoroughly lavaged and suctioned to remove any small meniscal fragments or debris that may have dropped into the joint as result of the resection.

- Types of meniscal excisions: O’ Connor separated meniscal excisions into three categories depending on the amount of meniscal tissue to be removed.
  
  o Partial Meniscectomy: In this type of meniscal excision, only the loose, unstable meniscal fragments are excised, such as the displaceable inner edge in bucket-handle tears, the flaps in flap tears, or the flaps in oblique tears. In partial meniscectomies, a stable and balanced peripheral rim of healthy meniscal tissues is preserved.
o **Subtotal Meniscectomy:** In this type of meniscectomy, the type and extent of tear require excision of a portion of the peripheral rim of the meniscus. This is the most commonly required in complex or degenerative tears of the posterior horn of either meniscus. Resection of the involved portion by necessity extends out to and includes the peripheral rim of the meniscus. It is termed subtotal because in most cases most of the anterior horn and a portion of the middle third of the meniscus are not resected.

o **Total Meniscectomy:** Total removal of the meniscus is required when it is detached from its peripheral meniscosynovial attachment, and intra-meniscal damage and tears are extensive. If the body of the peripherally detached meniscus is salvageable, total meniscectomy is not warranted and meniscal suture should be consider.

Admittedly, success rates are high [33] and complication rates low (0.27% to 2.8%). But Salzler [34] reported a complication rate of 2.8% and did not consider knee arthroscopy to be benign procedure. In contrast, since 2002 and more particularly 2013, several controlled randomized studied compared arthroscopic meniscectomy versus non-operative management (mainly by physiotherapy) [35] [36] [37] [38] [39] or " sham" surgery [32] [40]. The older studies, by Moseley and Kirkley concerned osteoarthritis knee and others knee free of macroscopic osteoarthritis. The meta-analysis by Thorlund and Kise’s recent study confirmed these finding [41] [42]. However, it should be noted that cross-over for failure of non-operative treatment in the randomized studies, however well conducted, involved biases and limitation to which the reader must be alert [43] [44].

9. **Postoperative Care**

Toe-touch weight bearing with the use of crutches is allowed for 48 hr until the patient is comfortable. Straight-leg raising exercise, ankle pumps, and range of motion exercise are started in recovery room and repeated hourly during the early postoperative period. Wall sets are started 3 to 4 days after surgery. Stationary bike and progressive low-impact strengthening exercise are started when postoperative swelling has resolved. Return to sport is allowed around 3 to 4 weeks.

10. **Discussion and Conclusion**

Many articles had been published regarding meniscal tears. After studying and analyzing all the methods and treatment of different articles, there is the possibility to cure by conservative treatment if patients get diagnosed earlier by different tests done by doctors in their clinical practises. Although the articles do not contain data and meta-analysis about this treatment, but have clearly focused on conservative treatment and advice of orthopaedic surgeon not to miss the meniscal tear during clinical practice. This review mainly aims on basic concept of meniscus tear and how to approach clinically and reach to proper diagnosis of meniscal tear, even experience of orthopaedic surgeon missed during
clinical examination which further leads to chronic tears of meniscus. This review had shortly reviewed all concepts and management, and treatment on meniscus tear. Knee brace and knee exercise are quite helpful for meniscal tear patient and also are helpful to the knee injured patient. The injury can heal within months. Surgery is rarely required only in most severe cases. However, minimal invasive surgical procedure (Arthroscopy) is an advance treatment for chronic meniscus tear. It is very difficult to diagnose meniscus tear clinically without having any investigation, if the diagnosis is done by having minimum investigation and earlier than conservative treatment will have better results, which is quite economic to the patient, they need not to be admitted to hospital for as there is no further issues related to their health.
