## Abstract

**Aim:** To present a rare occurrence of aortopulmonary fistula due to rupture of proximal aortic dissection in a 48-year-old woman. **Introduction:** Aortic dissection is defined as disruption of the medial layer provoked by intramural bleeding, resulting in separation of aortic wall layers and subsequent formation of a true lumen and a false lumen with or without communication. **Case Report:** A 48-year-old female presented with vague anterior chest discomfort, high blood pressure, systolic-diastolic murmur in the left sternal border with ECG changes of myocardial ischemia. Echocardiography revealed a dilated aortic root with intimal flaps, a leak into the pulmonary artery and regional hypokinesis with contractile dysfunction suggesting a proximal aortic dissection with rupture into the main pulmonary artery. **Discussion:** The etiology of aortic dissection was mostly hypertension in 80% of cases and aortopathies such as connective tissue disorders, inflammatory and idiopathic. Aortic wall stress is a major trigger of intimal tear and two-dimensional transthoracic echocardiography is an excellent, initial diagnostic gold standard to detect the dissecting flaps, especially in proximal aortic dissection. **Conclusion:** Blood pressure control is the mainstay of treatment and urgent surgery is indicated in proximal aortic dissection since there is higher chance of rupture with an increase in mortality.

## Keywords

Dilated Aortic Root, Intimal Flap, Aortic Insufficiency, Aortic Rupture, Aortopulmonary Fistula

## 1. Introduction

The aorta is a large elastic artery composed of three layers; the thin delicate intimal layer is lined by endothelium and can be easily traumatized; the thick middle layer is the media, composed of sheets of spirally arranged elastic tissue which

affords maximum tensile strength, smooth muscle cells and collagen. Adventitia is the outer layer composed of loose connective tissue and carries vasa vasorum which nourishes the outer half of the aortic wall including much of the media. The ascending aorta is 5 cm long and its lower segment; the aortic root is 3.3 cm, begins at the level of the aortic valve, extends to the sinotubular junction and the upper tubular segment joins with the aortic arch. Aorta may be considered as dilated if the diameter is >40 mm at the level of ascending aorta, 35 mm at the arch and thoracic descending aorta, and 30 mm at abdominal aorta. Aortic root dilatation predisposes to the dissection or rupture which accounts for 1% - 2% of deaths in industrialized nations [1]. The maximal internal diameter of ascending aorta in dissection is  $55.7 \pm 12.4$  mm (range 35 - 90 mm). Aortic dissection is not always associated with aneurysmal dilatation of aortic root [2]. The dissection may originate from an area of non-dilated aorta even in Marfan's syndrome, especially in children [3] as a result of abnormal vascular extracellular matrix protein, the fibrillin [4] due to mutation in fibrillin-1 gene [5] and also in a spectrum of overlapping diseases such as Goldberg syndrome, familial or isolated forms of aortic aneurysm, "Mass" phenotype which are collectively called as "Type-1 fibrillinopathies" [6] or structural defects in the pro  $\alpha$ -1 (III) of type III collagen in Ehler-Danlos syndrome (EDS) type IV (EDS vascular type). Mutation in other genes such as COL3A1 gene [7] is also reported in these connective tissue disorders.

Cystic medial necrosis (smooth muscle cell necrosis and elastic fiber degeneration with the presence of cystic spaces filled with mucoid material in the media) associated with connective tissue disorders was once believed to contribute to degeneration of the aortic media leading to aortic dissection most frequently in the ascending aorta (first few cms of ascending aorta and 90% found within 10 cm of aortic valve). Degenerative changes associated with aging result in breakdown of collagen, elastin, smooth muscle cell as well as an increase in basophilic ground substance contributing the histologic change of cystic medial necrosis associated with dissection. However, a study showed that a minority of patients with aortic dissection established medial degeneration [8]. Sometimes, these changes lead to weakening of the aortic wall and results in formation of fusiform aneurysm often involving the aortic root. The term annuloaortic ectasia was used to describe this condition which was first coined by Ellis *et al.* in 1961, occurs in 5% to 10% of patients with aortic regurgitation and the aortic root is bulbous, pear-shaped as shown in **Figure 1**, pyriform appearance or flask shaped. In syphilis, the spirochetes directly infect the aortic media during the second phase of the disease, most commonly involving the ascending aorta after a latent period of 5 - 40 years, destroy the muscular and elastic elements of the media and the inflammatory response is replaced by fibrous tissue that frequently calcifies. The medial destruction often results in progressive aneurysmal dilatation of the aortic root, only potentially causes aortic dissection in tertiary stage [9] and it has become a rarity today [10] as a result of aggressive antibiotic treatment at its early stage. Thus, aortic diseases such as aortic dilatation, aortic aneurysm,

**Figure 1.** Parasternal long axis view showing the leak into the LVOT (left ventricular outflow tract) as aortic regurgitation due to rupture at the site of annular support of the aortic valve.

annuloaortic ectasia, chromosomal aberrations (eg. Turner syndrome, Noonan syndrome), aortic arch hypoplasia, coarctation of the aorta, aortic arteritis, bicuspid aortic valve and hereditary connective tissue disorders (Marfan's syndrome) are well-established predisposing factors for the development of aortic dissection [11] [12]. Marfan's syndrome significantly shows fragmentation and degeneration of elastin and helical collagen fibers with defective biosynthesis and cross-linkage of collagen substance [13]. The contributing risk factors for aortic dissection [14] are shown in **Table 1**.

Mechanical forces contributing to aortic dissection include flexion forces at fixed sites, radial impact of pressure pulse, and the shear stress of the blood. Aortic dissection occurs in the region of aorta that is subjected to the greatest  $dP/dt$  (the rate of increase in pressure or the LV ejection force) and pressure fluctuation [15]. The hydrodynamic forces in the blood stream that are generated by the propagation of a pulse wave with a velocity increases from 4 - 5 m/s in the ascending aorta to 5 - 6 m/s in the abdominal aorta [16] and systolic BP during each cardiac cycle deliver kinetic energy to the aortic wall and the repeated motion of aorta related to contractile function of the heart results in flexion stress which are more marked in the ascending aorta and eventually leads to dissection and its propagation. Hypertension is one of the most significant triggers for aortic dissection in 72% - 90% of cases [17] and tends to be higher in distal dissections (70%) than proximal dissections (36%). Hypertension adds to a mechanical strain and the shearing forces exerting a longitudinal stress along the aortic wall contributing to the development of aortic dissection. Severe hypertension is relatively common during the period of hospitalization after an acute aortic dissection even without a prior history of hypertension and it may reflect marked increase in sympathetic tone, triggered by severe inflammation of aortic wall due

**Table 1.** Risk factors for aortic dissection.

Hypertension	
Genetically triggered thoracic aortic disease	
	Marfan syndrome
	Bicuspid aortic valve
	Loeys-Dietz syndrome
	Vascular Ehlers-Danlos syndrome
Congenital diseases/syndromes	
	Coarctation of the aorta
	Turner syndrome
	Tetralogy of Fallot
Atherosclerosis	
	Penetrating atherosclerotic ulcer
Trauma, blunt, or iatrogenic	
	Catheter/stent
	Intraaortic balloon pump
	Aortic/vascular surgery
	Motor vehicle accident
	Coronary artery bypass surgery/aortic valve replacement
Cocaine use	Catecholamine induced acute hypertension
Inflammatory/infectious diseases	
	Giant cell arteritis
	Takayasu arteritis
	Behet's disease (immune mediated small-vessel systemic vasculitis)
	Aortitis
	Syphilis
Pregnancy	Hypertension precipitates proximal aortic dissection and aortic rupture, commonly occurs during 3 <sup>rd</sup> trimester or during the first stage of labour

to dissection process rather than renal ischemia. Weightlifting is known to elicit profound hemodynamic stress on the wall of the aorta [18] and may predispose the younger persons to aortic dissection, particularly type I.

Classification systems are used to locate the aortic dissection and its extent. The Stanford classification was developed from a functional approach based on whether the ascending aorta was involved as shown in Table 2. Dr. Michael De-Bakey, a pioneer in vascular surgery developed a classification as shown in Table 3. Many cases of aortic dissection do not fit into these classifications since a dissection limited to aortic arch, proximal to left subclavian artery but not involving ascending aorta may not be classified as type A or type B. Therefore, it is prudent to simplify the classification into anatomical categories, the proximal aortic dissection refers to involvement of aorta proximal to the origin of left subclavian artery which may or may not extend distally and distal aortic dissection refers to the involvement of aorta distal to the origin of left subclavian artery. In 1999, a classification based on the pathophysiologic features of aortic lesion rather than its location by the European Society of cardiology [19] was shown in Table 4. Some authors state that type A dissections are confined proximal to brachiocephalic artery and type B dissections are confined distal to it.

**Table 2.** Stanford classification [20].

Type A	Dissection involves the ascending aorta and/or aortic arch, and possibly the descending aorta. The tear can originate in the ascending aorta, the aortic arch, or more rarely, in the descending aorta. It includes DeBakey types I and II
Type B	Involves the descending aorta or the arch (distal to the left subclavian artery), without the involvement of the ascending aorta. It includes DeBakey type III

**Table 3.** DeBakey classification—an anatomical description of aortic dissection [21].

Type I (68%)	Originates in ascending aorta and propagates at least to the aortic arch and often beyond it distally. It is most often seen in patients less than 65 years of age and is the most lethal form of the disease
Type II (10% - 15%)	Originates in the ascending aorta and is confined to it
Type III (25% - 30%)	Originates in the descending aorta and rarely extends proximally, but will extend distally. It most often occurs in elderly patients with atherosclerosis and hypertension
Type IIIa	Propagates proximally or distally, mostly above the diaphragm
Type IIIb	Propagates distally to the abdominal aorta

**Table 4.** Pathophysiological-ESC (European Society of Cardiology) classification.

Class 1	Classical aortic dissection with an intimal flap between true and false lumen
Class 2	Medial disruption with formation of Intramural haematoma/haemorrhage
Class 3	Discrete/subtle dissection without haematoma, eccentric bulge at tear site
Class 4	Plaque rupture leading to aortic ulceration, penetrating aortic atherosclerotic ulcer with surrounding haematoma, usually subadventitial
Class 5	Iatrogenic and traumatic dissection

Thus, it is recommended that acute aortic syndrome (AAS) are classified according to both lesion type and location [22].

A leak or rupture of the dissection process into the surrounding structures is rapidly fatal and so this case had been reported.

## 2. Case Report

A 48-year-old, hypertensive woman was admitted with sudden onset of palpitations and chest discomfort for 3 days duration. She skipped the antihypertensive medications for one week and experienced pain over the anterior chest without any migratory character or radiation and the pain was a vague discomfort rather than sharp and knife like. The pulse rate was 115 bpm and blood pressure 200/130 mmHg and no pulse or BP differentials in the extremities. General examination revealed no features of Marfan's syndrome. Physical examination revealed basal crackles over the lung fields and cardiac auscultation revealed "to-and-fro" systolic-diastolic murmur over the left second and third intercostal spaces mimicking grade 3/6 continuous murmur. Blood chemistry revealed normal. ECG revealed sinus tachycardia with ischemic changes as T-wave inversions in left pre-cordial leads as shown in **Figure 2**. X-ray chest revealed normal as shown in

**Figure 2.** ECG showing sinus tachycardia and ischemic changes as T-wave inversion in left precordial leads.

**Figure 3.** Emergency transthoracic 2D echocardiography revealed a dilated aortic root with a fibrosed intimal flap in the infero-medial aspect as shown in **Figure 4**, suggesting a chronic proximal aortic dissection and the aortic cusp was displaced from the annulus due to the tear of dissection. Another dissection flap was found in the supero-medial aspect of the aortic root as shown in **Figure 5**. A regurgitation jet in the LVOT (left ventricular outflow tract) as in **Figure 1** and a leak into the pulmonary artery as shown in **Figure 6** and **Figure 7** suggesting an aortic rupture with fistulation into the main pulmonary artery (aortopulmonary fistula). The patient was treated with IV nitroglycerin, labetalol 100 mg twice daily and diuretics. She was stabilised with medical therapy and planned for surgical correction, preferably Bentall's procedure with closure of the fistula, but died suddenly following a syncopal episode when begin to ambulant.

### 3. Discussion

#### 3.1. Review of Literature

The first case of aortic dissection was reported by Frank Nicholls in an autopsy

**Figure 3.** X-ray chest PA (postero-anterior) view-normal.

**Figure 4.** Parasternal long axis view showing the fibrosed dissection flap (intimal flap) in the infero-medial aspect of the aortic root, tear in the flap with displaced left aortic valve leaflet (LT AVL) teared from the annulus (AN) (double arrows). The dilated aortic root is pear-shaped.

report of King George II of Great Britain who died suddenly while straining in a toilet [23] on 25 October, 1760 and found a dissection in the aortic arch which ruptured into the pericardium [24] [25]. J. P. Maunoir, a French physician introduced the term “aortic dissection” in 1802. Thomas Bevell Peacock, a London cardiologist reported two series as 19 cases in 1843 and 80 cases in 1863 in the literature [26]. In 1924, Boyd reviewed 4000 autopsy reports of thoracic aortic aneurysms, finding 1197 cases of rupture with a 4% occurrence of aortopulmonary fistula [27]. In 1970, Bory and associates first reported an aortopulmonary fistula in a young woman [28]. In 1972, McCarthy and associates described an acute aortic dissection spreading through the ductus arteriosus to the pulmonary artery [29]. In 1995, Spier and Associates [30] described a unique case of rupture into both right ventricle and pulmonary artery with good outcome. In 1998, Atay and associates [31] reported a case of aortopulmonary fistula in a 73-year-old man. In 1999, a fistula was found between the false lumen and main pulmonary artery in a man underwent surgery for type A aortic dissection [32].

### 3.2. Pathophysiology

Aorta plays an important role in modulating left ventricular performance and arterial function throughout the entire cardiovascular system [33]. An increase in distending pressure during systole induces an increase in aortic dimension, which is directly related to the elastic properties of aorta. Aorta expands at a rate of 0.9 mm in men and 0.7 mm in women for each decade of life and a diameter larger than 6 cm are definitely more prone to rupture than smaller ones [34]. The ascending part of the aorta bears the largest pressure during the cardiac cycle [35] and its exposure to elevated pressures causes a tear in the intimal lining at the sites of greatest wall stress and results in dissection which propagates either anterograde or retrograde directions along the arterial wall. This entrance tear is the initiating event and blood enters into the media and splits the aortic lumen to form a double-channel aorta with a true and false lumen. The intima and the inner part of the media form the intimomedial flap which separates the false lumen from the true lumen and is composed mainly of aortic media delaminated from the aortic wall [36]. When blood flows into the false lumen, it may cause secondary tears in intima, blood can reenter the true lumen and creating additional communication between the true and false lumens in the distal aorta. The true lumen is usually small with high-velocity flow whereas the false lumen is larger with slower velocity and turbulent flow.

In autopsy series, as many as 13% of aortic dissections do not have an identifiable intimal tear [37]. In a minority of cases, the initiating event is the medial hemorrhage due to rupture of vasa vasorum. The intramural hematoma weakens the aortic wall and may progress either to outward rupture of the aortic wall in 35% of cases or to inward disruption of the intima, leading to communicating dissection in 3% to 5% of cases [38]. In penetrating aortic ulcer, an atheromatous plaque burrowing deeply through the intima into the media [39], the media is exposed to pulsatile arterial flow, which causes hemorrhage into the walls that

then leads to intramural hematoma [40] and adventitial erosion may cause rupture in 42% of cases [41]. These nonflap lesions are more common in the descending aorta especially in elderly hypertensive individuals [42]. Spontaneous resolution of an aortic intramural hematoma also has been reported [43]. The noncommunicating dissection is characterized by no entry tear and no flow in the false lumen, the false lumen is more often filled with thrombus and the differentiation from intramural hematoma may be difficult [44]. In the Japanese Guidelines for thoracic aortic dissection 2011, it is defined the non-communicating dissection as no communication between the false lumen and true lumen [45].

### 3.3. Clinical Perspectives

Von Kodolitsch *et al.* [46] identified the independent predictors of aortic dissection in a study of 200 patients. Aortic dissection is also classified according to its duration, defined as length of time from symptom onset to medical evaluation as acute (<2 weeks), subacute (>2 weeks and chronic (>6 weeks after the onset of pain)). The characteristic symptom of tearing pain in the chest was recognized in 1855 when a case was diagnosed in life. Pain is the most common symptom of acute aortic dissection in 96% of cases and those without pain are found to have chronic dissection [47]. The pain could be sharp (64%), tearing or ripping type (51%) or knife-like and its abruptness is the most specific characteristic feature. Pain is severe, unbearable at its inception and forces the patient to writhe in agony, fall to the ground or pace restlessly in an attempt to gain relief and has a tendency to migrate along the path of dissection in 17% of cases. The pain was located in anterior chest in >90% of cases of ascending aortic dissection, in interscapular area (36%) and back (53%) in descending thoracic aortic dissection, in abdomen and lower extremities (30%) when the dissection extending distally into the abdominal aorta. The initial pain of aortic dissection may be followed by a pain-free interval lasting from hours to days and then pain returns, is an ominous sign of impending rupture [48]. About 4% of acute dissections may be painless especially in diabetes and older individuals, making a delay in diagnosis [49]. Pulse deficits were reported in <20% of patients with aortic dissection (50% in proximal and 15% in distal dissections). It includes a significant difference in pulse volume (pulse differentials) and blood pressure (BP differentials) in two upper extremities due to partial compression of one or both subclavian arteries or a sudden loss of pulse with abrupt onset of chest pain raise a high suspicion of aortic dissection. The difference of >20 mmHg of systolic blood pressure may be found in 10% to 20% of unaffected individuals [50]. The presence of pulse differential is the most specific physical sign of aortic dissection in 38% of cases, may be transient, secondary to decompression of the false lumen by distal reentry into the true lumen or secondary to the movement of the intimal flap away from the occluded orifice. When a false lumen communicates with the true lumen, the duplication of pulse due to difference in flow rates in the true and false channels occurs and it is a rare physical finding of aortic dissection [51].

Myocardial infarction occurs in 1% - 2% of cases of aortic dissection second-

ary to the compression of coronary artery by the expansion of false lumen or the extension of dissection process. Involvement of right coronary artery is more common than the left one and, occasionally dissection and myocardial infarction occur concomitantly [52].

Aortic regurgitation accompanies in 18% to 50% of cases of proximal aortic dissection [53]. The mechanisms include dilatation of aortic root, annular dilatation, tearing of annulus or valve cusps, rupture of the annular support of the leaflets as shown in **Figure 8**, cusp prolapse due to pressure from asymmetric false lumen and physical interference of valve closure by intimal flap (intimal flap prolapse). In Marfan's syndrome, the aortic dilatation is confined to sinuses, effacement of sinotubular junction (failure to narrow at sinotubular junction) results in malcoaptation of leaflets and subsequent aortic regurgitation [54].

The risk of fatal rupture in patients with untreated proximal aortic (the aortic root and ascending portion) dissection is around 90%, and 70% of ruptures occur into pericardium, pleural cavity and mediastinum [55] leading to cardiac tamponade, left sided pleural effusion, hypotension and shock. Rare cases have been described in which the dissection eroded into the pulmonary artery and producing aorto-pulmonary fistula as in **Figure 7** [56]. It is important to rule out the presence of pseudohypotension due to obstruction of an aortic arch branch in aortoarteritis.

Raised concentrations of smooth muscle myosin heavy chain (a protein that released from damaged aortic medial smooth muscle) at higher levels ( $51 \pm 52.3$   $\mu\text{g/L}$ ) within 3 hours of symptoms) than in acute myocardial infarction ( $2.1 \pm 1.6$   $\mu\text{g/L}$ ) occurs in aortic dissection [57] and it is elevated ( $>2.5$   $\mu\text{g/L}$ ) from the normal level ( $0.9 \pm 0.4$   $\mu\text{g/L}$ ) in healthy individuals within 6 hours of the onset of dissection. It may become a useful initial step in triaging the patients with suspected aortic dissection provided that the patients present within 6 hours and

**Figure 8.** Apical view showing the leak into the LVOT (left ventricular outflow tract) from the site of rupture with normally attached aortic valve.

preferably within 3 hours. Its level is higher in proximal dissection than the distal and levels  $>10 \mu\text{g/L}$  shows 100% specificity for aortic dissection within 30 minutes of the assay. A blood D-dimer level  $<500 \text{ ng/ml}$  may rule out aortic dissection [58], but the AHA (American Heart Association) is not advising this test as evidence is still tentative [59].

Radiologically, mediastinal widening (bulge to the right with ascending dissection and to the left with descending dissection), localized hump on the aortic arch with widening of aortic knob distal to left subclavian artery and the separation of intimal calcification from the outer aortic soft tissue border by 10 mm, a finding on chest X-ray is called as “calcium sign” are the characteristic features of aortic dissection. About 12% to 20% of aortic dissections had normal chest X-rays as shown in **Figure 3**.

It is important to prevent misdiagnosis of thoracic aortic dissection. About 20% of patients with type A dissection had ECG evidence of acute ischemia or acute myocardial infarction [60] and erroneous administration of thrombolytic therapy may be unavoidable and hazardous. A compilation of reminders, symptoms, and risk factors called as Ritter rules (named for the actor John Ritter who died due to thoracic aortic dissection in September 11, 2003 which was misdiagnosed and treated as acute myocardial infarction) was formulated to predict the aortic dissection [61]. Aortopulmonary fistula should be suspected in a patient who had aneurysmal dilatation of aortic root and exhibits signs of heart failure.

### 3.4. Echocardiographic Features

Two-dimensional echocardiography is currently considered as the first non-invasive technique when aortic dissection is clinically suspected in an emergency room [62] and it has a sensitivity of 78% to 100% to diagnose type A dissection [63]. A dissection may extend weeks to months after its onset [64] and the tear is defined as a disruption of the flap continuity as shown in **Figure 4** with fluttering of the ruptured intimal borders [65]. The visualization of an intimal flap that separates the true and false lumens within the aorta is pathognomonic of aortic dissection [66] as shown in **Figure 4** and **Figure 5**. The two-dimensional echocardiography appears to be superior [67] in the recognition of an intimal flap and its utility is limited in visualization of a small circumscript dissection segment in the distal part of ascending aorta and anterior part of the arch, known as “blind spot” due to interposition of trachea and left main stem bronchus between the esophagus and the aortic arch. Two echocardiographic criteria for the diagnosis of aortic dissection are:

- a) Dilatation of one segment of the aorta.
- b) An abnormal linear intraluminal echo corresponding to the intimal flap [68] [69].

There are 3 types of intimal flap were identified as shown in **Table 5**.

In some cases, a linear echo criss-crossing or dividing the aorta perpendicularly is highly diagnostic of an intimal flap as shown in short axis image in **Figure 5**. If a thrombus is detected, the intimal flap is immobile and an aortic wall

thickness >15 mm suggests dissection with thrombus in the false lumen. The intimal tear is usually >5 mm, located at the level of ascending aorta in 60% to 65% of cases and this segment is more prone to rupture. The oscillating intimo-intimal flap always indicate an acute dissection without thrombosis of false lumen [70] and a parallel wall motion with absence of oscillating flap indicates a chronic dissection [71]. The intimal flap, an anatomical marker of identifying the false lumen may appear as “cobweb” or “beak” appearance as shown in **Figure 1** and **Figure 9** [72]. In acute dissection, the false lumen is more often larger and it is smaller in chronic dissections. The intimal flap is usually thick, may be calcified, less mobile and fibrosed in chronic dissection as shown in **Figure 4** and **Figure 9**. In rare instances, fistulous formation between the aorta and pulmonary artery may complicate dissection due to rupture as shown in **Figure 6**, **Figure 7**, **Figure 10**, and **Figure 11**. A disturbed diastolic flow signal was detected in the left ventricular outflow tract as aortic regurgitation as in **Figure 1**, **Figure 8** and **Figure 12** due to tear of annular support of leaflets at the site of rupture and this leak between aorta and pulmonary artery creating an acquired aortopulmonary fistula in this patient as shown in **Figure 6** and **Figure 7**.

**Table 5.** Types of intimal flap [73].

Type 1	Long (>1 cm), thin, bright, mobile in the lumen and undulating, vibrating or waving with a sail-like motion in M-mode recording (long oscillating flap)
Type 2	A long but minimally mobile linear echo which was duplicated and parallel to one or two aortic walls.
Type 3	A short, double linear image with a rapid systolic motion and high frequency oscillations

**Figure 9.** Apical view showing the dilated aortic root, normal aortic valve and dissecting membrane with a beak appearance.

**Figure 10.** Short axis view showing the leak into the aorta from the ruptured site.

**Figure 11.** Short axis view showing the progression of leak into the aorta.

**Figure 12.** CW (continuous wave) Doppler showing the leak jet mimicking as aortic regurgitation (AR).

A dilated pear-shaped aortic root as in **Figure 1** and **Figure 4** with regional wall motion abnormalities, particularly the inferior hypokinesia as shown in **Figure 13** due to right coronary occlusion is suggestive of acute type A aortic dissection with a dissection flap and small false lumen in the supero-medial aspect of the aortic root as in **Figure 5** in the short axis image in an already existing chronic disease as in **Figure 4**, leading to contractile dysfunction (EF 40%) as shown in **Figure 13**. The aortic arch and descending aorta appeared normal as shown in **Figure 14**.

**Figure 13.** M-mode LV study showing the inferior wall hypokinesia with contractile dysfunction (EF 40%).

**Figure 14.** Suprasternal window showing the normal aortic arch.

### 3.5. Management

Therapy for aortic dissection is directed to halt the progress of dissection process since lethal complications may arise from the the intimal tear and its subsequent course may result in vascular compromise or aortic rupture [74].

### 3.6. Medical Therapy

Since the arterial  $dP/dt$  reflects the force of LV ejection and it is the major stress acting on the aortic wall that contributes to both genesis and subsequent propagation of dissection, its diminution and reduction of systolic blood pressure are the two primary goals of pharmacological therapy. Acute dissection generally presents as a hypertensive emergency and the prime consideration of medical management is to maintain the mean arterial pressure around 60 to 75 mmHg and the systolic blood pressure to be reduced to values between 100 and 120 mmHg with an initial decrease should be at 20% [75]. Historically, Wheat *et al.* [76] first introduced the aggressive drug therapy for aortic dissection by originally using reserpine and guanethidine. A combination of beta blocker and a vasodilator (sodium nitroprusside) remains as a standard medical therapy recently. To reduce the  $dP/dt$ , an intravenous beta blocker, preferably propranolol 1 mg every 3 to 5 minutes (0.15 mg/kg) until a satisfactory beta blockade (heart rate 60 to 80 beats/minute) up to a total dose of 2 to 6 mg and then at 4 to 6 hours interval to maintain the adequate heart rate. In patients with labile arterial pressure or obstructive pulmonary disease, an ultra-short-acting beta blocker esmolol 500 mcg/kg IV bolus, followed by continuous infusion at a rate of 50 mcg/kg/minute and titrated up to 200 mcg/kg/minute is useful especially if surgery is to be planned. Labetalol, an alpha and beta adrenergic receptor antagonist is an alternative drug to lower both  $dP/dt$  and arterial pressure. It is given in an initial dose 20 mg IV over 2 minutes period, followed by 40 to 80 mg every 10 to 15 minutes until the heart rate and blood pressure have been controlled and then a maintenance dose of 2 mg/minute.

The most appropriate drug to provide pain relief is an opiate, the IV morphine sulphate. It reduces the force of cardiac contraction and the rate of rise of aortic pressure ( $dP/dt$ ), retards propagation of dissection; delays rupture and also prevent exacerbation of tachycardia and hypertension. AHA (American Heart Association) guidelines recommend beta blocker as a first-line treatment. Vasodilators should be given if systolic blood pressure >120 mmHg after beta blocker therapy and pain control. Appropriate rate control medications are mandatory before the initiation of vasodilator therapy as they induce reflex tachycardia and worsen the stress on the arterial wall. Calcium channel blockers and angiotensin converting enzyme (ACE) inhibitors are the acceptable alternatives in patients with contraindications to beta blockers. In refractory hypertension (persistent hypertension on the maximum dose of three different classes of antihypertensive drugs), an involvement of renal arteries with release of large amount of renin should be considered. In this setting, the most effective agent is IV ACE inhibitor, the enalaprilat given in an initial dose of 0.625 mg every 4 to 6 hours to con-

trol the blood pressure. Sublingual nifedipine is also successful to treat refractory hypertension associated with aortic dissection [77]. The efficacy of trimethaphan, a ganglionic blocker and a direct vasodilator is less predictable and it may cause tachyphylaxis, severe hypotension, urinary retention, and ileus. Hydralazine and minoxidil should be avoided since they produce a hyperdynamic response that would increase the  $dP/dt$ .

The potential problems encountered during medical therapy could be extension of dissection, aortic rupture and organ malperfusion resulting in hypotension and shock. In such cases attempts must be done to stabilize the patient with medical therapy which includes volume expansion with crystalloids and vasopressors (norepinephrine and phenylephrine) to titrate the mean arterial pressure at 70 mmHg. The extreme aggressive attempts at doing so may result in further propagation of false lumen [78] with adverse outcome, the aortic insufficiency and pericardial tamponade since both conditions are preload-dependent [79]. Therefore, treatment of shock associated with aortic dissection should be managed by rapid surgical intervention.

If coronary insufficiency occurs, nitrates may be used, but therapy with thrombolytic agents and aspirin should be avoided.

### 3.7. Surgical Therapy

The principal aim of cardiac surgery in type A aortic dissection is to obliterate the entry tear in the ascending aorta, thereby preventing flow into the false lumen, encouraging thrombosis of the false lumen and healing of the aortic dissection [80]. Definitive surgical therapy was first developed by Michael E. DeBakey, Denton Cooley, and Oscar Creech, the cardiac surgeons associated with the Baylor college of medicine, Houston, Texas in 1954 [81]. DeBakey developed aortic dissection himself at the age of 97 in 2005 and underwent surgery in 2006 [82]. The fenestration procedure is the first surgical approach to aortic dissection in which the dissected aorta was incised and a distal communication was created between the true and false channels thereby decompress the false lumen. This procedure is used in selected cases of dissection involving the descending aorta to relieve the renal or mesenteric or limb ischemia [83].

When the proximal aorta is fragile or badly torn or entire root is aneurysmatic, Bentall procedure, a radical approach is used mostly, in which a composite prosthetic graft (aortic valve plus ascending aorta tubular graft, *i.e.*, a prosthetic aortic valve sewn on to the end of a Dacron tube graft) facilitates replacement of both ascending aorta and aortic valve together and coronary arteries are reimplanted as buttons of aortic tissue into the graft wall [84] [85]. Bypass grafting of coronary arteries using saphenous vein segments is to be done when the coronary ostia were torn by the dissection.

The first successful repair of aortopulmonary fistula was reported by Giacobine and Cooley in 1960 [86]. Closure of the fistula results in immediate hemodynamic and symptomatic relief.

### 3.8. Interventional Therapy

Endovascular stent grafts are not indicated for repair of the ascending aorta or aortic arch and it is a standard treatment in most cases of distal aortic dissection. The fenestration/stent treatment could be used in unstable proximal dissection as a palliative treatment in high surgical risk patients. There are two endovascular techniques used to manage the acute vascular complications secondary to aortic dissection as follows.

a) Percutaneous balloon fenestration of the intimal flap which involves crossing an intact intimal flap with a wire, passing a balloon-tipped catheter over the wire, and then expanding the balloon to tear a hole in the intimal flap which allows the blood to flow from the false lumen into the true lumen, thereby decompress the distended false lumen.

b) Percutaneous stenting of the affected arterial branch whose flow has been compromised by the dissection process, in which a stent is deployed within the lumen supplying the branch vessel to hold the lumen, opens by displacing the intimal flap towards and overcoming the pressure from the other lumen by a balloon fenestration procedure.

Percutaneous aortic graft stenting are currently available and shows better results than surgical graft stenting [87]. Aortic stenting is primarily used to supplement fenestration as well as to reduce the dissection flap. In high grade compression of true lumen supplying to major aortic branch, stenting may play a role to enlarge the compressed lumen and to increase the distal flow. An average stent grafts are 3.5 cm (2.4 - 4.5 cm) in diameter and 10.5 cm (preferably <15 cm) long. After deployment of a stent, a balloon incorporated in the system, allows further apposition of the stent struts to the wall of the true lumen and to occlude the intimal tear rather than wrapping of the intimal flaps to the wall of the false lumen. Attempting to eliminate tears and reentries starting at the beginning of the intervention may improve the prognosis. Use of candy-plug technique with an excluder aortic extender for distal occlusion of a large false lumen aneurysms in chronic aortic dissection and an Amplatzer vascular plug II as a sealing button to obliterate the false lumen have been reported recently [88], [89]. "Tear-oriented surgery" for acute Type A dissection and open stent-grafting (OSG-Frozen®, Japan, Life line, Tokyo) or frozen elephant trunk (FET) [90] involves substituting "distal anastomosis to the descending aortic suture by fixation with the stent-graft" in aortic arch surgery was launched in Japanese patients in 2014 [91].

### 3.9. Outcome

The IRAD (International Registry of Acute Aortic Dissection) study reported mortality rate of 27% for type A aortic dissection in 464 patients undergone surgical therapy [92] and in experienced centers, the long-term survival rate was >90%. The Japanese association of thoracic surgery reported overall hospital mortality was 9.1% in 2013 in a study of 4444 patients with acute type A aortic dissection who underwent surgical correction.

### 3.10. Prophylactic Measures

The accepted critical aortic root diameter of 5 - 5.5 cm at any age even in infancy, the prophylactic replacement of aortic root should be performed at a diameter of 5.5 cm and this general agreement is not applicable to other segments of the aorta. All patients should receive lifelong antihypertensive medications including beta blockers, the blood pressure should not exceed 130 mmHg systolic for both children and adults [93] and to be titrated to <120/80 mmHg.

### 4. Conclusion

Aortic dissection is the most frequent form of acute aortic syndrome and it is a serious condition that needs immediate medical and surgical care. It is relatively rare, occurring at a rate of 3 per 100,000 people per year. It often presents as a two-step process. The first event is characterized by severe pain and pulse loss and thereafter, the bleeding stops. The second event sets in when the pressure exceeds a critical limit and rupture occurs. The risk of rupture is 10 times higher in hypertensive individuals. Aortopulmonary fistula is an exceedingly rare complication of aortic dissection and only 13 cases (4 in acute, 8 in chronic dissections and one found during surgery of type A dissection) have been reported up to 1999. Another case of aortopulmonary fistula was reported at this hospital due to rupture of proximal aortic dissection in a 48-year-old woman in 2017. In ascending aortic dissection, 75% die within 2 weeks without surgery and so urgent immediate surgery is mandatory in Type A aortic dissection.

Scientific Research Publishing

**Submit or recommend next manuscript to SCIRP and we will provide best service for you:**

Accepting pre-submission inquiries through Email, Facebook, LinkedIn, Twitter, etc.

A wide selection of journals (inclusive of 9 subjects, more than 200 journals)

Providing 24-hour high-quality service

User-friendly online submission system

Fair and swift peer-review system

Efficient typesetting and proofreading procedure

Display of the result of downloads and visits, as well as the number of cited articles

Maximum dissemination of your research work

Submit your manuscript at: <http://papersubmission.scirp.org/>

Or contact [crmc@scirp.org](mailto:crmc@scirp.org)
