Abstract

Aim: To present the heterotopic ossification of left-sided heart valves due to rheumatic inflammation and biomineralization. **Introduction:** Calcification in the region of mitral-aortic continuity is significant at its origin and etio-pathogenesis. The etiology of valvular calcification may be divided into 3 groups, namely, inflammation, degeneration and metabolic disturbances. Calcification of cardiac valve leaflets is most often due to rheumatic etiology in tropical nations. **Case Report:** A 52-year-old male developed sudden onset of light-headedness and palpitations due to atrial fibrillation. Transthoracic 2D echocardiography revealed calcification of anterior mitral leaflet and aortic valve which resembles a bone-like structure and the patient was advised double valve replacement. **Conclusion:** It was known that the cellular mechanisms play an important role in its genesis and therapeutic strategies are targeted to reverse this process by understanding its biological mediators.

Rheumatic Mineralization, Mitral-Aortic “J-Shaped” Calcification, “Mushroom Shaped” Calcified Bicuspid Aortic Valve, Hutchinson-Gilford Progeria Syndrome, Therapeutic Strategies

1. Introduction

A calcified valve is the hardening of valve due to the deposition of calcium salts at the site of wear-and-tear and damage. It is important to remember that any valve can become calcified. However, calcification is more likely to affect the valves on the left side of the heart (mitral and aortic valves) since they experience greater pressure, more wear-and-tear damage with increased risk of deposition of calcium phosphate salts, known as dystrophic calcification. This senile valve calcification occurs on the mitral valve at the age of 50 - 70 years and on the aortic valve at 70 - 90 years of age. Calcification can occur earlier in life when

associated with rheumatic heart disease and heavy calcification was seen in severely damaged valves by the rheumatic process. Since the disease process is complex and involves several different cell types, it is important to understand the cellular and matrix architecture of a normal heart valve. The valve endothelial cells (VECs) line the outer surface of the valve and maintain homeostasis by regulating permeability, paracrine signaling and function as a barrier to limit inflammatory cell infiltration and lipid accumulation. The valve interstitial cells (VICs) are the predominant cell type within the fibrosa, spongiosa and ventricularis layers of the valve and secrete extracellular matrix, including collagen, elastin, and glycosaminoglycan. The fibrosa consists of fibroblasts, circumferentially arranged fibrillar collagen fibers (type I and type III) and serves a load-bearing function. The spongiosa is predominantly found at the base of the leaflet and it is a layer of loose connective tissue containing mesenchymal cells, fibroblasts, mucopolysaccharides and it resist the compressive forces within the cusps. Ventricularis contain elastin fibers, oriented perpendicularly to the collagen and it reduces the radial strain. The normal aortic valve is made up of 3 cusps and its arrangement results in even distribution of mechanical stress to the valve ring and the aorta [1]. At their base, the valve leaflets are attached to a dense collagenous network, called the annulus, which facilitate their attachment to the aortic root and the dissipation of mechanical force. The anterior mitral leaflet is in direct continuity with left half of non-coronary cusp and the adjacent third of left coronary cusp of aortic valve. The mitral-aortic intervalvular fibrosa is the junctional tissue between the elements of mitral and aortic valves, called as mitral-aortic membrane or curtain. It is relatively avascular and offers little resistance to infection [2].

Historically, calcification of valves has been attributed to prolonged “wear and tear” and age-related valvular degeneration, and recent evidence suggests that it is the result of active inflammatory process [3] leading to osteogenesis by involving biochemical, humoral and genetic factors. The mechanism of valvular calcification is similar to skeletal bone formation and it is the most common manifestation of rheumatic heart disease. The anterior mitral leaflet-aortic cusp continuity region was particularly affected by this mineralization process and so this case had been reported.

2. Case Report

A 52-year-old male was admitted with sudden onset of palpitations and he had a history of rheumatic fever during childhood. He developed the symptoms of exertional dyspnea at the age of 40 years and took penicillin prophylaxis for some period and then dropped it for 10 years. He married at the age of 26 years and had 5 healthy children. General examination revealed no stigmata of progeria syndrome. Pulse rate was 75 bpm and irregular. His blood pressure was 110/70 mmHg. Cardiac examination revealed a heaving apical impulse in the left 5th space at anterior axillary line, varying intensity of first heart sound with a mid-diastolic murmur at the apex and grade 4/6 mid-systolic murmur well heard at

the apex as a conduction from right second intercostal space where its intensity is maximum due to “Gallavardin” phenomenon (harsh murmur of aortic stenosis change its quality and musical at the apex due to transmitted high pitched components and low pitched components were transmitted to neck vessels- as a dissociation between harsh, noisy, low frequency components at the right second space, transmitted to neck vessels as “carotid shudder” and high frequency musical components at the apex as a “musical murmur”). Blood chemistry revealed normal including the lipid profile. ECG revealed atrial fibrillation and LVH (left ventricular hypertrophy pattern) as shown in **Figure 1**. X-ray chest revealed concentric LVH and ascending aorta dilation as shown in **Figure 2**. Transthoracic 2D echocardiography revealed the dense calcification of anterior mitral leaflet and aortic valve as shown in **Figures 3-6** as a result of rheumatic mineralization. The patient was treated with verapamil tablets 40 mg three times daily to keep the rhythm under control and advised early double valve replacement along with lifelong penicillin prophylaxis.

3. Discussion

3.1. Review of Literature

Lazare Riviere, a French physician in 1663, identified large caruncle-like masses

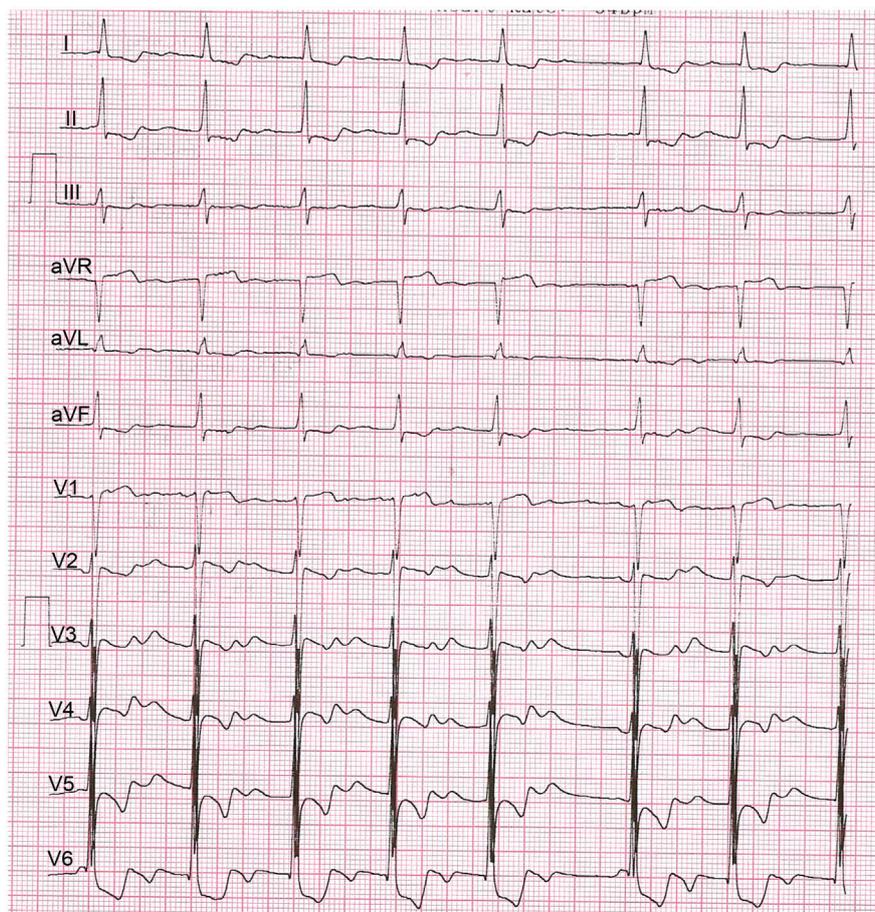

Figure 1. ECG showing the “atrial fibrillation” with LVH (left ventricular hypertrophy).

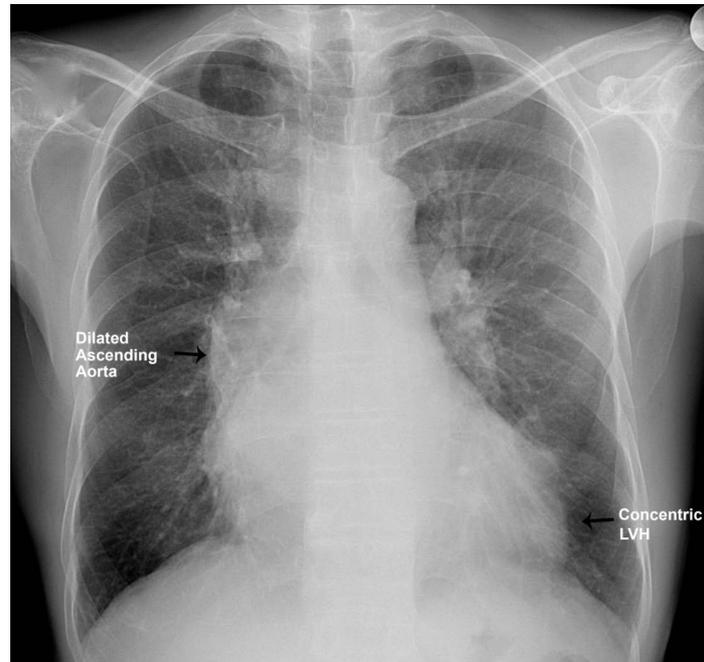

Figure 2. X-ray chest PA (postero-anterior) view showing concentric LVH (left ventricular hypertrophy-right black arrow) and dilated ascending aorta-left black arrow).

obstructing the left ventricular outflow to the aorta in necropsy findings as an earliest description of calcific aortic stenosis [4] and the calcified mass was originally attributed to endocarditis. In 1846, Hass suggested a degenerative process occurred within the valve itself to initiate ossification. In 1904, Moenckeburg found that the aortic valve calcification occurred as a result of calcium deposition on the valve cusps due to degeneration within the layers of valve leaflets or

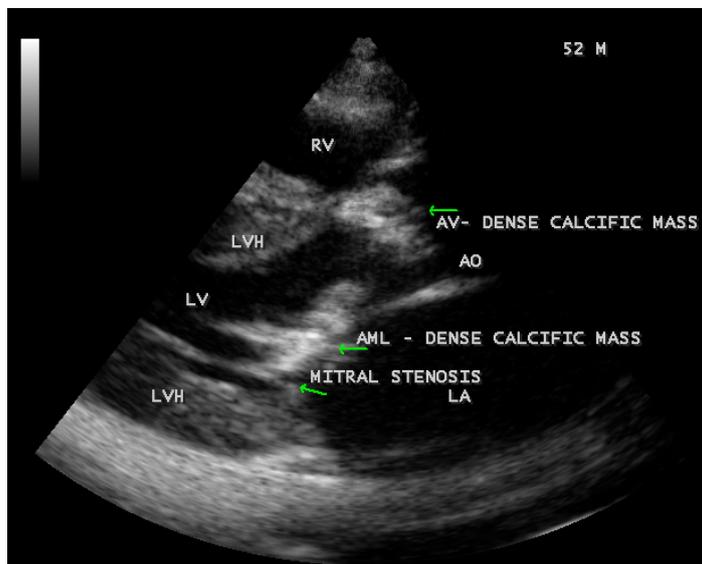

Figure 4. Parasternal long axis view showing the calcific bar of anterior mitral leaflet and aortic valve in a 52-year-old male.

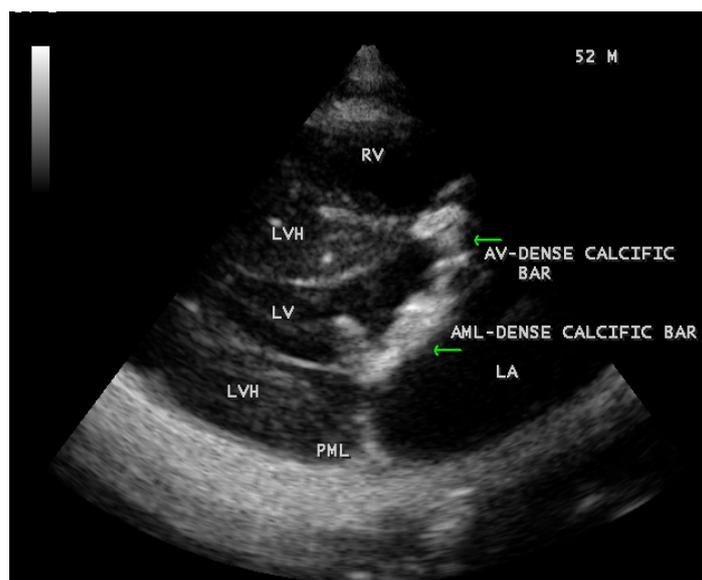

Figure 5. Parasternal long axis view showing the J-shaped appearance of mitral-aortic calcification in a 52-year-old male.

extension of sclerotic changes of aorta to valve cusps. In 1924, Dr. Carey Coombs described the inflammatory lesion in the rheumatic valve leaflets and the presence of new vessels developing within the valves [5]. In 1931, Christian first described that aortic stenosis with calcification of the cusps was possibly of rheumatic origin [6]. In 1938, Clawson, Noble and Lugkins stated that the “calcified aortic nodular deformity” was predominantly of a rheumatic nature [7]. In 1939, Dry and Willius concluded that the etiologic factor of calcification was rheumatic [8] and Hamburger and Saphir found evidence for both a rheumatic and nonrheumatic origin [9]. In 1961, Edwards discussed the occurrence of calcification in stenotic rheumatic valves [10].

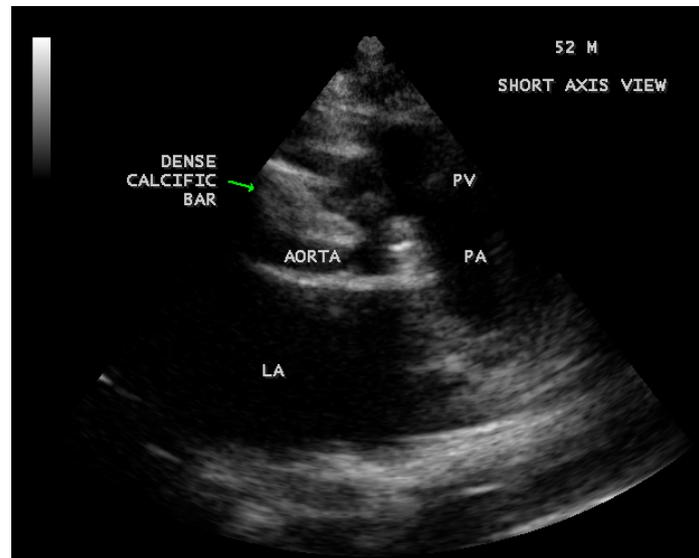

Figure 6. Short axis view showing the dense calcific bar in the aortic valve visible as calcium stone in a 52-year-old male.

3.2. Pathogenesis

Rheumatic heart disease is the most common cause of valvular heart disease in tropical nations such as India. Rheumatic valve calcification is not a random passive process, but it is a regulated, inflammatory cellular process associated with the expression of osteoblast markers and neoangiogenesis. Early stage of calcification is in a manner akin to atherosclerosis. Once the osteoblast activity has been established, the disease progression is more likely to be regulated by the mediators of calcium homeostasis [11]. A similar osteoblast-like process that occurs in degenerative calcific valve develops in the calcific process of rheumatic valves [12]. The cellular and molecular mechanisms that involve the valve, circulating and bone marrow derived cells have been implicated in the pathogenesis of calcification. The cellular differences between the rheumatic and degenerative lesions are the intense inflammatory infiltrate and VEGF (vascular endothelial growth factor) expression in areas of neoangiogenesis found in rheumatic valves compared to degenerative valves. The cardiovascular risk factors such as exposure to biochemical (hypercholesterolemia, hyperglycemia) or mechanical (hypertension) may disrupt the normal cellular and matrix architecture of the valve, produces an inflammatory tissue milieu, atherosclerosis like lesions, osteoblastic transformation and calcification process. The key mediators of valve calcification are shown in **Table 1**.

These mediators promote neoangiogenesis, extracellular matrix remodeling, fibrosis and calcification of valve leaflets.

Calcification of heart valves is an immune-inflammatory disease process. The rheumatic involvement produces an inflammatory tissue environment that disrupts the endothelial layer of valve leaflets in a mechanism similar to that in atherosclerosis. The endothelial disruption may allow the lipids, including low-density lipoproteins, apolipoprotein B, (a) and E₂ to penetrate and accumulate in

Table 1. Key mediators of valve calcification.

Key mediators of valve calcification
VECs (valve endothelial cells) to mesenchymal transition
VICs (valve interstitial cells) to osteoblast-like bone forming cells
Matrix vesicle formation gives rise to microcalcific nodules
Lipid accumulation

areas of inflammation and undergo oxidative modification. These oxidative lipoproteins are highly cytotoxic, capable of stimulating intense inflammatory activity and subsequent mineralization [13]. The VECs (vascular endothelial cells) are activated and the expression of adhesion molecules that facilitate recruitment and transendothelial migration of monocytes which differentiate into macrophages, and infiltration of T-lymphocytes and α -actin expressor cells. The macrophages release matrix metalloproteases and cysteine endoproteases that lead to degradation of collagen and elastin in the valve matrix to disrupt the normal valve architecture [14]. The T-cells release proinflammatory cytokines, including transforming growth factor- β , tumor necrosis factor- α and interleukin-1- β which induce myofibroblast activation and cellular proliferation, ultimately help to stimulate and establish subsequent fibrotic and calcification processes that drive increasing valve stiffness [15] [16]. Increased levels of activated CD8 cells (cytotoxic T-cells or natural killer cells) and memory effector cells in patients with calcified valves may indicate a systemic adaptive immune response on valve calcification [17]. Lrp5, a coreceptor of the family of LDL receptors, has been found to regulate cellular proliferation and bone formation in valvular tissues [18]. Genetic bone markers have been found to be important in the development of osteoblast bone formation, a process that precedes calcification [19]. Lp(a) levels mediate the effect of SN rs10455872 in the gene LPA in valvular calcification. The kringle IV type 2 (KIV-2) repeats at LPA locus, which encode apolipoprotein (a) and its variation determines the plasma Lp(a) levels. NOTCH 1 on chromosome 9q34-35 is a susceptibility locus for bicuspid aortic valve and accelerates valvular calcification [20]. At the site of endothelial damage, the endothelial progenitor cells participate in the repair process by transiently establishing residence and secreting factors that facilitate proliferation and migration of resident endothelial cells [21]. In calcified valves, these progenitor cells are dysfunctional and express increased proapoptotic caspase-3 activity and decreased telomeric-repeat binding factor-2 (TERF2) expression, indicating progenitor cell senescence [22]. The VECs (valvular endothelial cells), lose the endothelial cell properties, no longer express endothelial-specific markers such as cadherin, pie-racque-like pleomorphism characteristic of mesenchymal cells or myofibroblasts and express α -smooth muscle actin, type I collagen and vimentin [23]. The transforming growth factor- β , transcription factor *Msx2* and β -catenin signaling increase the motility and migration of these “transformed” VECs into the surrounding tissues [24]. Once the endothelial-to-mesenchymal transition (EnMT) occurs, the BMP 2 and 4 (bone morphogenic proteins) secreted by the activated

endothelial cells stimulate the calcification by activating Smad and Wnt/B-catenin signaling and upregulate the expression of osteochondrogenic transcription factor Msx2 and the faster osteoblast transcription factor Runx2 [25]. Once Runx2 is expressed, the cells are committed to an osteoblast lineage, upregulated the expression of calcification-related proteins (osteopontin, bone sialoprotein II, osteocalcin) and undergo calcification [26]. A subpopulation of VICs (valve interstitial cells) become activated in the inflammatory zone of the valve and differentiated into myofibroblasts. These myofibroblasts secrete matrix metalloproteinases which play a role in the restructuring of valve leaflet matrix and responsible for accelerated fibrosis in this process [27]. Under the influence of signaling pathways, Wnt-3-Lrp5- β catenin [28], OPG/RANK/RANKL pathway (osteoproteogen/receptor activation of nuclear factor kappa B/RANK ligand [29], Runx-2/NOTCH1, activated by BMPs, the myofibroblasts undergo differentiation into osteoblasts, which subsequently coordinate calcification as a part of a highly regulated process akin to new bone formation and mineralize to form calcific nodules on the valves. The local environment drives the mesenchymal progenitor cells to undergo osteogenesis differentiation, elaborate bone matrix in the valve [30] and capable of contributing to valve calcification.

The transition of valvular cells to an osteoblast-like phenotype is not a mutually exclusive process and these osteoblast-like cells may actively generate vesicles or undergo apoptosis to accumulate calcium and form microcalcifications. Matrix vesicles (100 to 300 nm) are derived from plasma membrane of smooth muscle cells, encapsulate the calcium inhibitors (MGP-vitamin K dependent matrix Gla protein, Fetuin A-a liver derived protein, osteoproteogens), sequester, render them inactive [31] and serve as a nidus for calcium deposition [32]. Calcifying nanoparticles (10 - 500 nm in size) consistent with nanobacteria [33], [34] which nucleate, crystallize and function as a nidus for matrix calcification [35]. The activated matrix metalloproteinases (1, 2, 3 and 9) and cathepsins (S, K, V and G) degrade the collagen and elastin, compromises valve integrity, augment the inflammatory response and allows for the expansion of calcified nodules [36]. By the end stage of the disease, maturation of valve calcification occurs with lamellar bone and hemopoietic tissue and it is sustained by neoangiogenesis. The new vessels localizing to the region of inflammation and surrounds the calcific deposits. Both intercellular adhesion molecule-1 and vascular cell adhesion molecule-1 expressions are increased in these vessels, suggesting that they act as an important portal of entry of inflammatory cells [37]. The mast cells get degranulated in calcified valves and release tryptase which degrade the angiogenesis inhibitor endostatin [38] and down regulation of local angiogenesis inhibitors such as chondromodulin-1 and pronomodulin-1 have been occurred. Once neovascularization has been established, the network of newly formed vessels, expressing the endothelial markers Tie-2, vascular endothelial growth factor receptor-2, smooth muscle α -actin, facilitate rapid transit of inflammatory cells and procalcific signaling molecules and, these inflammatory lesions in rheumatic valvular disease is associated with angiogenesis and osteogenesis which may

contribute disease progression and valvular mineralization.

3.3. Echocardiographic Features

The genesis of calcification in aortic valve is always rheumatic [39] and the calcific extension to the mitral valve resembles J-shaped as shown in **Figure 5** and **Figure 13**. Calcification resembling a string of pearls in both aortic and mitral valves are typical of endocarditis. Calcification of mitral-aortic membrane has been reported as highly suggestive of radiation-induced lesions [40] and a pathologic echo density of anterior mitral leaflet is its characteristic feature [41]. But the dense calcification of anterior mitral leaflet as a bone-like structure was observed due to rheumatic mineralization as shown in **Figures 3** along with calcification of aortic valve as in **Figure 4** and **Figure 5**. The calcified aortic valve resembling as “calcium stone” was shown in short axis view in **Figure 6**.

The degenerative disease, as an aging process frequently involving the aortic and mitral valves and the central fibrous body is called as ‘Lev’s disease. Lene-gre’s disease primarily involves the conduction system without affecting the fibrous skeleton of the heart. Both these conditions mostly results in isolated chronic heart blocks in adults. Degenerative calcification of mitral annulus may cause annular mitral stenosis in elderly and the difference between the annular mitral stenosis and rheumatic mitral stenosis [42] was shown in **Table 2**.

3.4. Therapeutic Strategies

3.4.1. Statins

Lipoprotein (a) has been shown to accumulate in both early and end-stage aortic valve lesions and to co-localize with calcium deposition [43]. In atherosclerosis, inflammation and lipid deposition are the key components in both development of arterial plaque and its stability. Adverse events are predominantly related to plaque rupture, and much of the benefit from statin therapy is due to plaque stabilization and a thickening of the fibrous cap. Lowering Lp(a) levels during early - stage aortic valve disease, with the use of either niacin [44] or novel specific Lp(a) inhibitors [45] can slow the progression to aortic stenosis. Lipid-lowering with HMG-Co A reductase inhibitors (statins) have been shown to decrease inflammatory cell infiltration, osteoblast bone markers (alkaline phosphatase and Runx2) and downregulate lipoprotein receptor-related protein 5/ β -catenin signaling to decrease valve calcification in rabbit models [46]. Despite these findings, 3 large-scale clinical trials (SEAS-Simvastatin and Ezetimibe in Aortic

Table 2. Difference between annular mitral stenosis and rheumatic mitral stenosis.

Annular mitral stenosis (Figure 7)	Rheumatic mitral stenosis (Figure 8)
Degenerative	Inflammatory
Heavy calcification at the base of leaflets	Calcification of leaflets mainly at the tips
Leaflet tips are free	Leaflet tips thickened
Leaflets open without dooming restriction	Restricted diastolic opening of leaflets with dooming

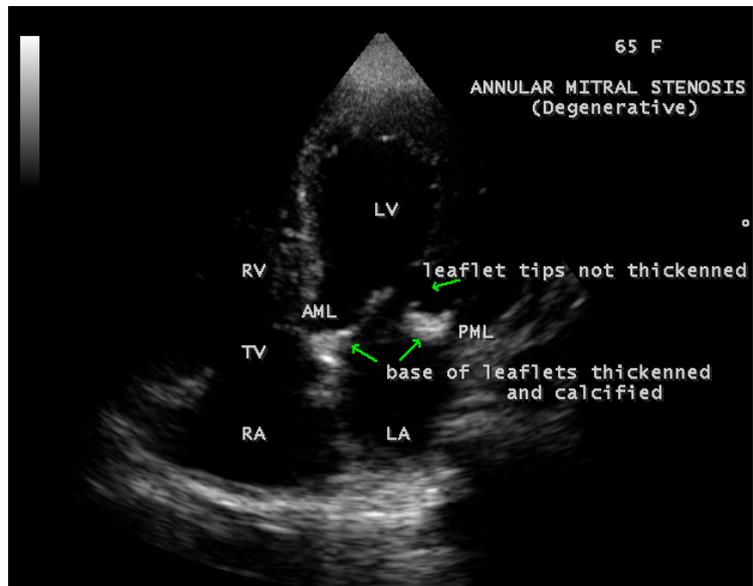

Figure 7. Apical view showing the annular mitral stenosis with basal leaflet calcification in a 65-year-old female.

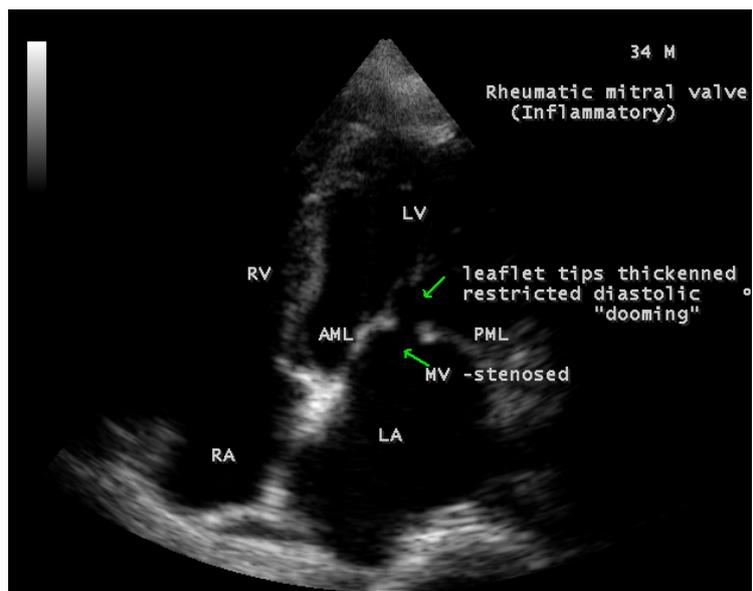

Figure 8. Apical view showing the rheumatic mitral valve in a 34-year-old male (Rheumatic mitral stenosis).

Stenosis [47], SALTIRE-Scottish Aortic Stenosis and Lipid Lowering Trial [48] and ASTRONOMER-Aortic Stenosis Progression Observation: Measuring Effects of Rosuvastatin [49]) failed to show a benefit for statins to limit the progression of aortic valve calcification. Also, statins are known to promote osteoblast differentiation and calcification [50]. Lowering of lipid levels may decrease calcium deposition and halt the progress of valve calcification, but did not reverse the established calcification or valve dysfunction [51]. When the valvular interstitial cells (VICs) become osteoblast-like cells, statins may actually have a procalcifying effect.

3.4.2. Warfarin

Warfarin is an inhibitor of γ -carboxylase and vitamin K epoxide reductase, inhibits MGP (matrix Gla protein- an inhibitor of bone morphogenic protein (BMP) signaling [52]) activity and was shown to promote valvular calcification [53].

3.4.3. Fetuin A

It is a potent circulating inhibitor of calcification [54], acts by binding the cluster of calcium and phosphate to stabilize these ions and prevent uptake by cells and its deficiency was associated with valvular calcification [55]. Therapies with fetuin A show a potential in inhibition of valvular calcification [56].

3.4.4. ACE Inhibitors

Tissue angiotensin-converting enzyme (ACE) and angiotensin II are upregulated in stenotic aortic valves and angiotensin receptors have been identified on valve myofibroblasts [57]. Areas of fibrosis are observed to co-localize with areas of myocyte apoptosis due to ischemia since the density of capillary network does not expand sufficiently as in physiologic hypertrophy and drive the decompensation of the hypertrophic myocardial response. There is an evidence that angiotensin receptor blocker therapy inhibits the development of atherosclerosis as well as myofibroblast and osteoblast trans-differentiation in rabbit aortic valves suggests that this drug class may be helpful in slowing aortic stenosis progression [58]. The blood pressure-lowering effect of ACE inhibitors decreases the mechanical stress and strain on the aortic valve and play a role in reducing inflammation, stabilizing plaque formation and mitigating the fibrotic process [59], an integral part of hypertrophy related to polymorphism of ACE 1/D gene.

3.4.5. Denosumab

The OPG/RANK/RANKL axis appears to have a central regulatory role in both calcification and osteoporosis, which coordinate calcium homeostasis via the action of osteoblasts and osteoclasts. OPG (osteoprotegerin) is a decoy receptor of RANKL, a potent stimulator of osteoclast differentiation and bone resorption [60]. Increased expression of RANKL (receptor activator of nuclear factor kappa B ligand) and reduced levels of OPG have been also observed in stenotic aortic valves similar to osteoporosis. Inactivation of OPG in mice develops extensive vascular calcification [61]. The development of anti-RANKL monoclonal antibody denosumab promising a strong rationale in the treatment of aortic stenosis.

3.4.6. Bisphosphonates

Calcification is a critical process in determining the progress of valvular stenosis and a overlap in pathophysiology between the aortic stenosis and osteoporosis provide a rationale for drugs such as bisphosphonates to reduce the valvular calcium, especially in patients with renal failure and bioprosthetic valves [62] [63]. However, it had no effect on freedom from aortic valve replacement or survival [64].

3.5. Gene Transfer

By understanding the cell biology of valvular calcification, gene transfer or cell-based therapies are investigated to modulate the cellular mechanism of calcification. The expressing Runx2 in VICs (valvular interstitial cells) commits these cells to an osteoblast-like phenotype. Gene transfer of small interfering RNA that targets Runx2 using adenovirus or recombinant nonviral vectors have been shown to prevent calcification both in vitro and in vivo [65] [66]. Heterotopic ossification (HO), which was first identified by Dejerne and Ceillier in 1918 [67] and it is characterized by pathologic endochondral bone formation at nonskeletal sites. Angiogenesis and osteogenesis are highly coupled during bone development. In the process of osteoblast differentiation, a set of bone specific genes (ALP-alkaline phosphatase, osteocalcin) are activated. Run-related protein 2 (Runx2) is a key regulator of these genes, cooperate with BMP-specific R-smads and it is considered as a molecular switch (myoblasts to osteoblasts phenotype) in osteoblast biology. Hypoxia is able to upregulate BMP₂ in osteoblasts via the activation of Hif1 α signaling pathway. Inhibition of Hif1 α (hypoxia induced factor 1 α) leads to reduce vessel formation, which may facilitate migration of host mesenchymal stem cells to the bone regeneration site. Synergistic inhibition of endochondral bone formation by silencing the angiogenic factor (Hif1 α) and osteogenic factor (Runx2) by using the RNA interference technology, allow to design more targeted therapies to inhibit angiogenesis and osteogenesis [68]. miRNAs (microRNAs) have essential roles in osteoblast differentiation and heterotopic ossification. miR-203 is involved in these processes by repressing Runx2 expression in the post-transcriptional level. Therapeutic overexpression of miR-203 in osteoblasts may reduce heterotopic ossification and even prevent this disorder [69]. Cotransduction of small or short interfering RNA (siRNA) against Runx2 and Hif1 α to inhibit heterotopic ossification have been evaluated. TNP-470 is an antiangiogenic agent that inhibits the neovessel formation and TNP-70 inhibits the biological activity of BMP₂ in early stage of bone induction. A potent delivery of a nanocomposite consisting of serum-stable DOTAP/ siRNA/PPAA-g-1% Jeffamine formulation was shown to halt the osteogenic switch driven by BMP₂ by silencing the Runx2, the downstream mediator of BMP₂ [70].

3.6. Investigational Therapy

Osteoclast-like cells are identified in calcified lesions, which in turn capable of resorbing mineral deposits [71]. Thus, strategies to promote osteoclast recruitment or stimulate differentiation of monocytes and macrophages toward an osteoclast phenotype are the areas of active investigation.

Strategies by delivering stem or progenitor cells via direct injection of small molecule inhibitors, osteoclasts, osteoclast-like cells or molecules that promote the transition of resident monocytes/macrophages towards an osteoclast lineage or viral vectors encoding inhibitory RNA (Runx2, Msx2) in areas of aortic valve lesions or to ischemic myocardium using a NOGA-guided catheter system [72] are under investigation.

3.7. Lonafarnib

Mutations in laminin A gene results in the production of a mutant lamin A protein, progerin, a component of nuclear envelope which becomes unstable, leading to cell death prematurely. The syndromes associated with these defects are called as “laminopathies” (Hutchinson Gilford Progeria Syndrome (HGPS), Wiedemann-Rautenstrauch syndrome, Restrictive dermopathy) [73]. In progeria, calcific aortic stenosis represents a degenerative premature aging process and principally involving the anterior mitral leaflet and proximal aortic valve cusps [74]. Systemic hypertension is common and appears before the child reaches the age of 5, and high mortality due to myocardial infarction and heart failure may occur.

Farnesylation is essential for the function of both mutant and nonmutant lamin A protein, including progerin. Lonafarnib is a farnesyl transferase inhibitor that blocks the posttranslational farnesylation of prelamin A, an experimental drug under trials [75]. Another treatment attempted is a combination of two molecules-Zoledronic acid and pravastatin.

3.8. Interventional Therapy

Balloon mitral valvotomy (BMV) is the procedure of choice for severe mitral stenosis when the valve morphology is feasible. However, BMV is contraindicated in bicommissural calcification since it results a high probability of leaflet tear with acute severe mitral regurgitation. BMV can be performed safely and successfully in unicommissural calcified mitral valves [76].

An emergency percutaneous transatrial balloon mitral commissurotomy is a life-saving procedure in a valve with unfavourable morphology, presented with cardiogenic shock in critical calcific mitral stenosis [77] [78].

3.9. Transcatheter Valve Implantation

TAVR (transcatheter aortic valve replacement) was approved by FDA (Food and drug administration) for high risk surgical candidates in June 2012. There is an increase in risk of stroke due to thrombotic embolic material from the calcified valve tissue and vascular damage results in severe paravalvular regurgitation, which is poorly tolerated in hypertrophied left ventricle leading to increase in mortality [79]. The surgical risk for mitral valve replacement is very high due to the comorbidities and technical challenges related to calcium burden. Guerrero, et al reported the first-in-human percutaneous implantation of a balloon-expandable transcatheter valve in a native mitral valve [80]. The use of newer aortic THV technologies such as Lotus (Boston Scientific Corporation) and direct flow valves (direct flow medical) in the mitral position for severe MAC (mitral annular calcification) [81] with improved outcomes were observed [82].

3.10. Surgical Therapy

Aortic valve replacement surgery remains the only established treatment for symptomatic aortic stenosis patients [83]. Hemodynamically significant asymp-

omatic patients will develop symptoms within 5 years, the issues of medical management and surgical correction may pay a close attention to the researchers [84]. Presence of moderate or severe valvular calcification identifies the patients with poor prognosis who may benefit from early valve replacement before the development of symptoms [85] and it is to be determined whether this benefit outweighs the risk of surgery [86].

Calcific mitral stenosis with severe mitral annular calcification may present a different high risk to the surgeon. Extensive debridement of calcium may increase the risk of paravalvular leakage and bleeding. Bypass of the mitral valve with a valved conduit is another option for the treatment of severe calcific mitral stenosis [87].

Bioprosthetic valves are generally recommended for patients > 65 years and there is also greater usage in younger patients due to lack of necessity of chronic anticoagulation. The Ross operation (replacement of aortic valve with a pulmonary autograft and replacement of the pulmonary valve with a homograft) is an alternate for adolescents, young adults, including woman who wish to become pregnant and it is not favoured by the majority of surgeons due to complexity of the procedure, but excellent outcomes occurred in centers with expertise in this procedure [88].

3.11. Screening of Population

Aortic valve calcification extending to anterior mitral leaflet was shown in **Figure 9** in a 64-year-old male. A bicuspid aortic valve calcification extending to anterior mitral leaflet was shown in **Figure 10** and it is “mushroom” shaped [89] or bulbous (clublike or circle) configuration [90] as in **Figure 11** in a 34-year-old male. J-shaped [91] mitral-aortic calcification was shown in **Figure 5** in a 52-year-old male and in **Figure 13** in a 60-year-old male. Aortic valve calcification

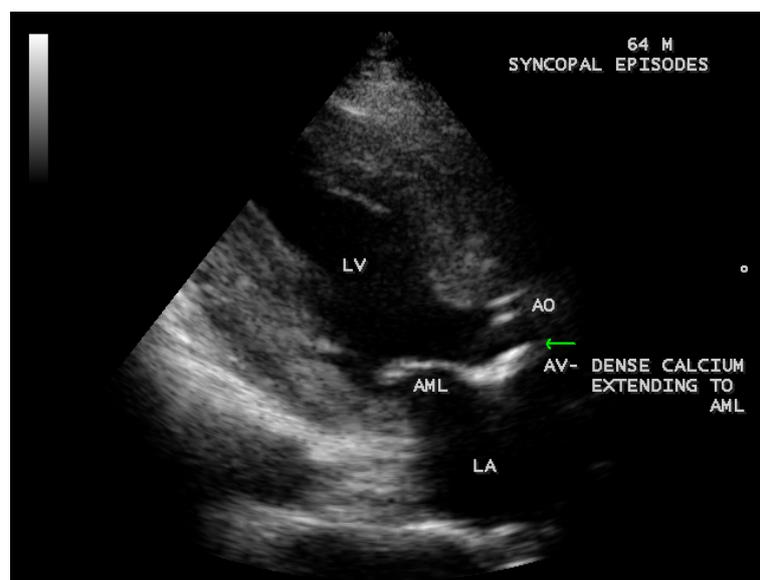

Figure 9. Parasternal long axis view showing the extension of aortic valve calcification to anterior mitral leaflet in a 64-year-old male.

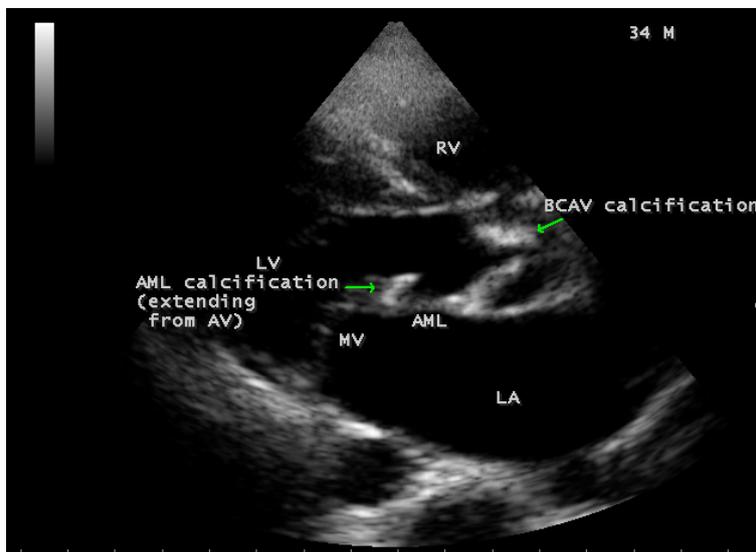

Figure 10. Parasternal long axis view showing dense calcium in aortic valve and anterior mitral leaflet in a 34-year-old male.

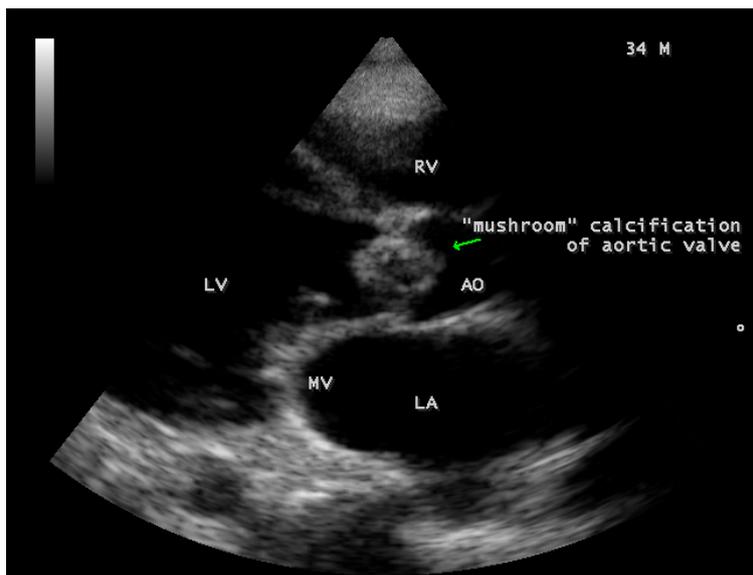

Figure 11. Parasternal long axis view showing the "mushroom" shaped calcification of Bicuspid aortic valve in a 34-year-old male.

resembling as "calcified amorphous tumor" [92] as in **Figure 12** in a 58-year-old male. Calcification of aortic valve and anterior mitral leaflet was shown in **Figure 15** in a 5-year-old child having phenotypic features of Hutchinson-Gilford Progeria syndrome as shown in **Figure 14** with bicuspid aortic valve regurgitation as shown in **Figure 16** and **Figure 17** and AML (anterior mitral leaflet) calcification in a newborn as in **Figure 18** and **Figure 19** due to rheumatic etiology rather than degenerative change of premature aging.

4. Conclusion

Calcification was common in valvular heart disease of inflammatory genesis.

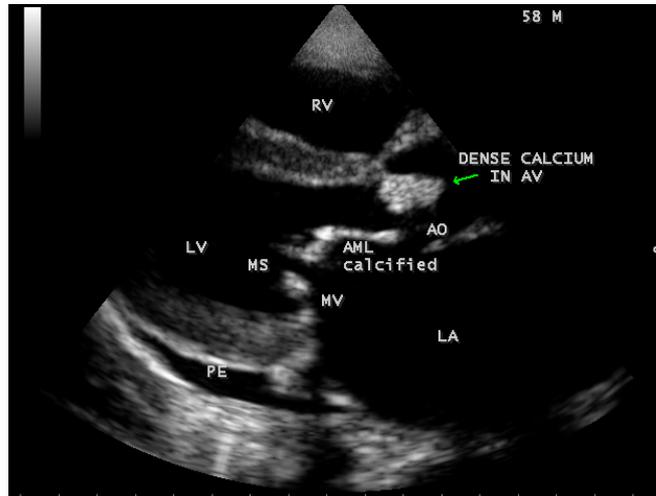

Figure 12. Parasternal long axis view showing the dense calcium in aortic valve mimicking as ‘calcified amorphous tumor’ in a 58-year-old male.

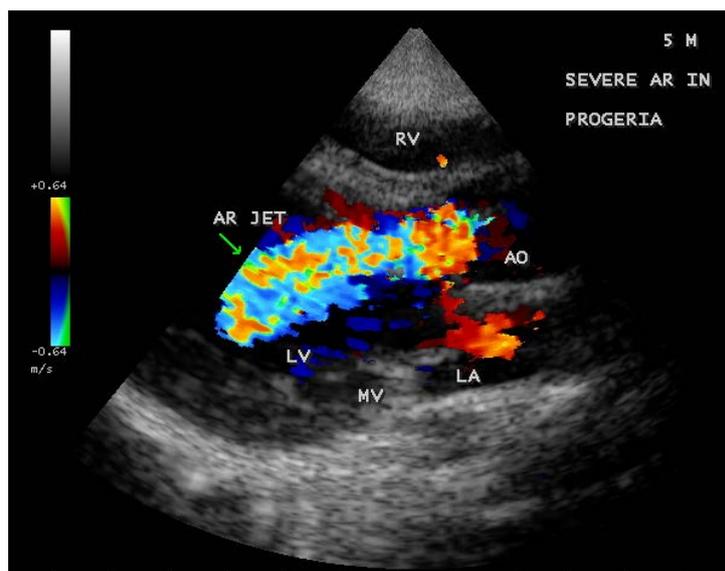

Figure 16. Color Doppler Imaging showing Severe aortic regurgitation in Progeria in a 5-year-old male child.

Most of them were localized to the mitral valve (47%), only in aortic valve or both in 38% of cases and it is mostly rheumatic in 80% of cases. Degenerative calcification of mitral ring was seen in 5% to 10% of cases. It is now clear that there is an active biology that leads to stiffening and calcification of valve leaflets [93] and so the valvular calcification is a biologic process. At present, therapeutic targets focused on cellular events to inhibit the process of calcification are under investigation. There is an association of rheumatic mineralization of mitral-aortic continuity and anterior mitral leaflet in Hutchinson-Gilford progeria Syndrome as shown in **Figures 14-19** was found in this region of Thoothukudi

Submit or recommend next manuscript to SCIRP and we will provide best service for you:

Accepting pre-submission inquiries through Email, Facebook, LinkedIn, Twitter, etc.

A wide selection of journals (inclusive of 9 subjects, more than 200 journals)

Providing 24-hour high-quality service

User-friendly online submission system

Fair and swift peer-review system

Efficient typesetting and proofreading procedure

Display of the result of downloads and visits, as well as the number of cited articles

Maximum dissemination of your research work

Submit your manuscript at: <http://papersubmission.scirp.org/>

Or contact crcm@scirp.org
