Abstract

Under the condition of simulated formation temperature and pressure, the compression and shear wave velocity of the tuffaceous conglomerates and rock-fragment sandstones of the reservoirs in K1t, k1n group of Cretaceous system in Tanan are measured. The effects of lithology, mineral content, density, porosity, shale content, and water saturation on the acoustic velocity of the athrogenic rock are studied. Within the limits of our observation, some rules are found: (1) the velocity of the fine tuffaceous conglomerates is remarkably greater than that of the tuffaceous rock-fragment sandstones with good physical property; (2) the compression velocity increases with fragment content, and decreases with quartz and feldspar content in the mud; (3) the compression velocity increases with density, especially, in tuffaceous rock-fragment sandstones, the velocity keeps a good relation with density in form of power function; (4) compression and shear wave velocity decreases with porosity and shale content, velocity of the tuffaceous rock-fragment sandstones keeps a good relation with porosity and shale content in form of negative linear function, but effects of shale content is only 1/5 to 1/10 of that of the porosity, hence can be neglected; (5) with porosity increases, compression wave velocity is relatively sensitive to fluid alternation, and the rang in which velocity varies keeps positive correlation with porosity. The result provides a foundation for the research of seismic and logging data evaluation approaches in athrogenic rock reservoirs, Haita basin.

Tuffaceous Rock-Fragment Sandstones, Acoustic Velocity, Porosity, Shale Content, Density, Water Saturation

1. Introduction

Haita Basin is a part of Central Asia-Ancient Aulacogen, which belongs to Eergu'Na-Greater Khingan Range tectonic zone. Tongbomiaof Formation and Nantun Formation in the lower Cretaceous of Zhalaianuoer group develop a large number of oil-bearing tight tuffaceous conglomerate and medium to low porosity and permeability rock-fragment sandstone reservoirs, which forms the main area for improving the production and has great po-

tential for prospecting [1]. At present, due to the lack of adequate understanding of the factors that affect the velocity of the volcano clastic rock in Haita Basin, the seismic and logging data can't be applied to predict the lithology of rock, calculate the porosity and detect the oil and gas effectively. Therefore, a detailed research on the influencing factors of velocity in the volcano clastic rock in Haita Basin is needed.

Until now, many researches have been done on the velocity properties and influencing factors of velocity (lithology, physical properties, fluid properties, density and environmental factors) in the sedimentary reservoirs. For instance, Wyllie (1956) proposed time average equation [2], Simmons (1964) gave the general linear relationship between the acoustic velocity and the component of rock and its density [3], Ma and Jie combined compressional wave velocity and shear wave velocity with density by least square method and proposed general Gardner Equation in 2005 [4], critical porosity was proposed by Nur *et al.* in 1992 [5], Han (1986) established empirical relationship for clastic rock to describe the influence of lithology and physical properties on the acoustic velocity [6], Biot (1956) and Gassmann (1951) obtained the equation to describe the influence of fluid on the rock acoustic velocity [7] [8], many other equations are also established based on them to describe fluid effect (such as Macko-jizba Formula [9]), Garden (1974) proposed the power function relationship between the acoustic velocity and density [10], Gan (2002) [11], Ma and Wu (2006) [12], Mavko (1998) [13], Han and Nur (1986) also carried out the experiments to investigate the influence of pressure and temperature on the velocity and its physical mechanism. However, few researches are done on volcano clastic rock and there are not many related papers. Schön (1996) [14] did a lot of statistical work on the acoustic velocity data of igneous rock and found that, the compressional wave velocity decreases with the increase of SiO₂ in the rock, Khatchikian (1982) [15] combined density, neutron and acoustic logging curves to determine the lithology of igneous rock and calculated the porosity of reservoirs.

The compressional and shear wave velocities of conglomerate and tuffaceous rock-fragment sandstone in Tanan were measured in this paper. The influences of lithology, mineral content, density, porosity, clay content and fluid saturation on the compressional and shear wave velocity are then analyzed, which provide the experimental foundation for employing seismic and logging data to predict the lithology, calculate porosity and recognize the fluid type.

2. Geological Characteristics of Volcano Clastic Sandstone Reservoirs

The core samples are obtained from Nantun Formation and Tongbomia Formation of Cretaceous in Tanan. Through the thin section analysis, it shows that the core samples belong to tuffaceous conglomerate, tuffaceous rock-fragment sandstone and tuff. The sandstone is mainly composed of quartz, feldspar and magmatite debris, the void space in the sandstone is filled by tuff. The samples have low degree of sorting and the degree of weathering is moderate to high, the roundness of the grains is mainly subangular and subangular-subround. The samples are supported by grains or clay, the contact types between the grains are no contact to point contact and point contact to line contact, the porosity types belong to original granular porosity and granular increment porosity, the samples are pore cemented. Among the samples, the tuffaceous rock-fragment sandstone has better physical properties than the other samples (the average porosity is 9.96%, the average permeability is 28.01 mD, the shale content is low), it is the main reservoir of this area. The tuffaceous conglomerate with better physical properties can also be the good reservoirs. Appendix 1 gives the results of thin section analysis.

3. Experimental Methods

3.1. The Measurement of Porosity, Permeability, Clay Content and Density

The porosity and permeability of samples are measured by CMS300 which is made by CORELAB Company of US. Under the simulated formation pressure (effective pressure is 25 MPa), the average porosity of the samples ranges from 0.02% to 21.19%, the average value is 6.21%, the permeability is distributed between 0.01 mD and 793 mD, the average value is 12.61 mD. The shale content is determined by MASTERSIZER-2000 Laser Particle Size Analyzer, the shale content ranges from 14.2% to 38.6%, the average value is 24.18%. The density of core samples is calculated using the mass of the core samples, the matrix volume and void space volume measured by CMS300. The measurement results are shown in Appendix 2.

$$\rho = \frac{m}{V_g + V_{por}} \quad (1)$$

where ρ is the density, g/cm^3 ; m is the mass of the samples; V_g , V_{por} are matrix volume and void space volume respectively, cm^3 .

3.2. Measurement of Acoustic Velocity

The acoustic velocities of core samples are measured by Multi Parameter Measurement System Under HPHT made by China University of Petroleum (East China). The measurement system is showed in **Figure 1(a)**. From the **Figure 1(a)**, we can see that the system is composed of four parts: hydraulic pump, temperature control unit, sample length measurement unit (micro displacement sensor) and data acquisition (**Figure 1(b)**), the velocity of the core samples can be measured under the simulated formation temperature ($\leq 150^\circ\text{C}$), and pressure (confining pressure, axle pressure and effective pressure ≤ 70 MPa). Ultrasonic Pulse Transmission Method is employed in the measurement of compressional and shear wave velocity. The acoustic velocity of the medium is calculated through the ratio of the length of transmission L to the arrival time t subtracted the system zero time t_0 , *i.e.*

$$V = L/(t - t_0) \quad (2)$$

where V is the acoustic velocity, m/s ; L is the length of the core samples, m ; t is the arrival time of the sound wave; t_0 is the zero time of the system, s . The frequencies of the wafers for compressional and shear wave are 1.2 MHz and 0.6 MHz, respectively. The frequencies of detectors for compressional and shear wave are 0.25 MHz and 0.12 MHz, respectively. The relative uncertainty for the measurement of compressional wave velocity is 0.3% - 0.9%, that for shear wave velocity is 0.8% - 1.4%. In this experiment, the compressional and shear wave velocities of the dry, brine bearing (the salinity is 5000 mg/L) and oil bearing (the density of the simulated oil is 0.798g/cm^3 , the viscosity is $3.52\text{ mPa}\cdot\text{s}$) samples are measured under the formation condition (temperature is 90°C , confining pressure is 50 MPa, the porosity pressure is 25 MPa). The measurement results are showed in Appendix 2.

4. The Analysis of the Factors That Affect the Acoustic Velocity

4.1. The Influence of Mineral Content and Lithology on the Acoustic Velocity

The influences of quartz, feldspar, magmatite debris and tuff on the compressional and shear wave velocities of dry core samples are presented in **Figure 2**. The lithology and mineral content are determined by thin section. The results show that the compressional and shear wave velocities decrease with the increase of the content of quartz and feldspar as a whole, but they increase as the content of magmatite debris increase. The content of tuff is found to have little relationship with the acoustic velocities. Among all the core samples, the velocities of the tight tuffaceous conglomerate are found to be obviously higher than those of the tuffaceous conglomerate and tuffaceous rock-fragment sandstones with good physical properties, through careful analysis, it is believed that it is mainly because of the low content of quartz ($\leq 10\%$) and high content of magmatite debris ($\geq 60\%$) in the tight tuffaceous conglomerate. Some of the data points in the **Figure 2** do not fit the alllover trend, it is maybe due to the different geometry, distribution, cementation of the minerals and the porosity between the mineral grains.

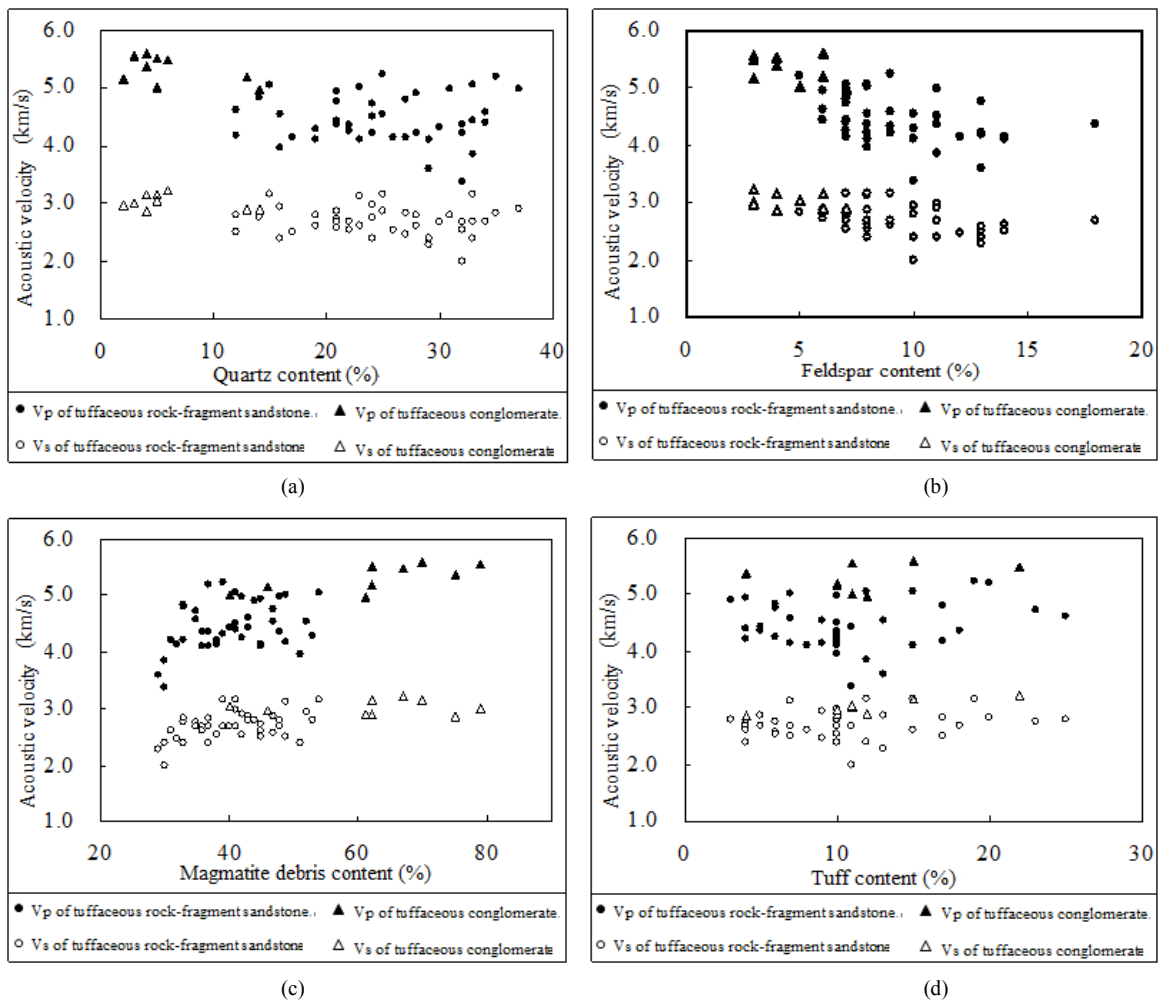

Figure 2. Compressional and shear wave velocities versus content of Quartz (a); Feldspar (b); Magmatic rock debris (c) and Tuffaceous miscellaneous base (d).

4.2. The Influence of Density of Core Samples on the Velocities

Figure 3 shows the cross-plot of the compressional and shear wave velocities versus the density of core samples ρ . The results show that the compressional and shear wave velocities of the core samples increase with their density. The data points with relative high compressional and shear wave velocities in **Figure 3** are tuffaceous conglomerate (it is showed in the ellipse of the upper right side of **Figure 3**). The tuffaceous rock-fragment sandstones and tuffaceous conglomerate can be separated by the compressional velocities as a whole and the value is about 5300 m/s. **Table 1** is the relationship between the density of tuffaceous rock-fragment sandstones ρ and the acoustic velocities. It is found that the difference between the correlation coefficient of the fitting formula obtained from general Gardner Formula and that obtained from Gardner Formula is not large, the former just improves a little. With the lack of shear wave velocities, we can only use compressional wave velocities to inverse the density ρ , it can also get good results. Ma and Xie (2005) also got similar results.

4.3. The Influence of Porosity and Shale Content on the Acoustic Velocity

Through the literature review [16]-[19], we can see that the compressional and shear wave velocities of samples decrease with the increase of porosity, the influence of shale content on the acoustic velocities is much more complicated, for the sandstone with good consolidation, the increase of clay content will lead to the decrease of acoustic velocities, but it will cause a slight increase in the acoustic velocities for the sandstone with weak consolidation. Generally speaking, the shale content is the leading reason for the scattering of the data points in the

(b)

Figure 3. Compressional wave (a) and shear wave (b) velocities versus density.

Table 1. The fitting equation between density and compressional or shear wave velocities.

Status of Samples	Fitting Formula (V_p)	Coefficient	Fitting Formula (V_s)	Coefficient	General Gardner	Coefficient
Dry	$\rho = 1.095 V_p^{0.537}$	R = 0.86	$\rho = 1.506 V_s^{0.482}$	R = 0.85	$\rho = 1.218 V_p^{0.318} V_s^{0.222}$	R = 0.88
Brine bearing	$\rho = 1.332 V_p^{0.408}$	R = 0.81	$\rho = 1.995 V_s^{0.246}$	R = 0.82	$\rho = 1.697 V_p^{0.157} V_s^{0.158}$	R = 0.87
Oil bearing	$\rho = 1.314 V_p^{0.418}$	R = 0.87	$\rho = 1.839 V_s^{0.314}$	R = 0.82	$\rho = 1.306 V_p^{0.427} V_s^{0.006}$	R = 0.87

Note: The unit for acoustic velocity is m/s , that for the density of the samples is g/cm^3 .

velocity-porosity cross-plot. According to the linear empirical relationship gave by Han (1986) [20], the relationship between the compressional and shear wave velocities and the porosity-shale content is fitted (**Table 2**).

$$V = a + b\phi + cV_{sh} \quad (3)$$

where V is the acoustic velocity, km/s ; ϕ is the porosity of the samples, %; V_{sh} is the shale content of samples, %; a , b , c are the constants obtained by the experiments.

The study shows that there is an obvious negative linear correlation between tuffaceous rock-fragment sandstone and the porosity, shale content ($R \geq 0.85$), the influence of shale content on the compressional and shear

Table 2. Fitting formula of density and compressional and shear wave velocities on porosity and clay content.

Status	Expression	Correlation coefficient
Dry sample	$V_p = 5.12 - 6.98\phi - 0.4V_{sh}$	R = 0.86
	$V_s = 3.33 - 4.91\phi - 0.82V_{sh}$	R = 0.87
Brine bearing	$V_p = 5.45 - 6.12\phi - 0.5V_{sh}$	R = 0.87
	$V_s = 3.28 - 5.7\phi - 0.75V_{sh}$	R = 0.89
Oil bearing	$V_p = 5.46 - 7.18\phi - 0.65V_{sh}$	R = 0.90
	$V_s = 3.31 - 5.1\phi - 0.83V_{sh}$	R = 0.88

wave velocities is only about 1/5 - 1/10 of that of porosity. Therefore, the influence of shale content on acoustic velocities is very weak and can be ignored. This result is different from Han's which is based on the experimental data from 75 shale sandstone samples in Gulf of Mexico, his result shows that the influence of shale content is about 1/3 of that of porosity. Through careful analysis, the main reason for the difference may be that the shale in the volcanic clastic rock is mainly composed of tuff, the main component of tuff is volcanic debris, whose acoustic velocity is much higher than that of clay and is near to that of matrix, this will weaken the influence of shale content to a certain degree. Until now, there are only experimental results for the tuffaceous rock-fragment sandstone in the cretaceous of Haita Basin, it needs further research on this aspect.

4.4. The Influence of Pore Fluid on the Acoustic Velocity

The influence of pore fluid on the acoustic velocity is investigated through fluid substitution. The theories usually used in the analysis are Biot Theory and Gassman Equation. The difference in compressional and shear wave velocities between brine-bearing and oil-bearing versus porosity is showed in **Figure 4**.

From **Figure 4**, we can see that the absolute value of the difference in compressional and shear wave velocities between brine-bearing and oil-bearing samples increases with the porosity. The compressional wave velocity of brine-bearing samples is higher than that of oil-bearing, the absolute change rate ranges from 0 - 300 m/s, the relative change rate (relative to the compressional velocities of oil-bearing samples) is near 6% at most, the samples are sensitive to the fluid substitution. The shear wave velocities of the brine-bearing samples are relative small than that of oil-bearing samples, the absolute change rate ranges from 0 - 120 m/s, the relative change rate is small, the response of fluid substitution is not obvious.

According to Biot Theory and Gassmann Equation, the change of compressional velocity after fluid substitution is mainly because of the difference in the bulk modulus of the fluid, the bulk modulus of the water is higher than that of the oil, so the brine-bearing core samples have higher velocities than the oil-bearing core samples. For the change of the shear wave velocities, Wang and Nur (1986) attributed it to the change of the density and viscosity in the samples. As the fluid substitution won't cause obvious change in the shear modulus, the decrease of the density or the increase of viscosity will both increase the shear wave velocity.

5. Conclusion and Discussion

The research is done to investigate the influence of lithology, mineral content, density, porosity, shale content and fluid saturation on the compressional and shear wave velocities, the following conclusions can be obtained.

- 1) The compressional and shear wave velocities increase with increase of the content of magmatite debris, but they decrease with the increase of quartz and feldspar content. It is due to the difference in elastic modulus and density between magmatite and quartz, feldspar.
- 2) Tight tuffaceous conglomerate has low content of quartz ($\leq 10\%$) and high content of magmatite debris ($\geq 60\%$), its velocity is obviously higher than the tuffaceous rock-fragment sandstone with good physical properties. We can use 5300 m/s as the lower velocity bound to separate the compressional velocity of tight tuffaceous conglomerate and tuffaceous rock-fragment sandstone.
- 3) The compressional and shear wave velocities increase with the increase of density. There is a good power relationship between the acoustic velocity and the density. In the seismic and logging evaluation work, the power statistic relationship established by experiments can be applied to predict the shear wave velocity and

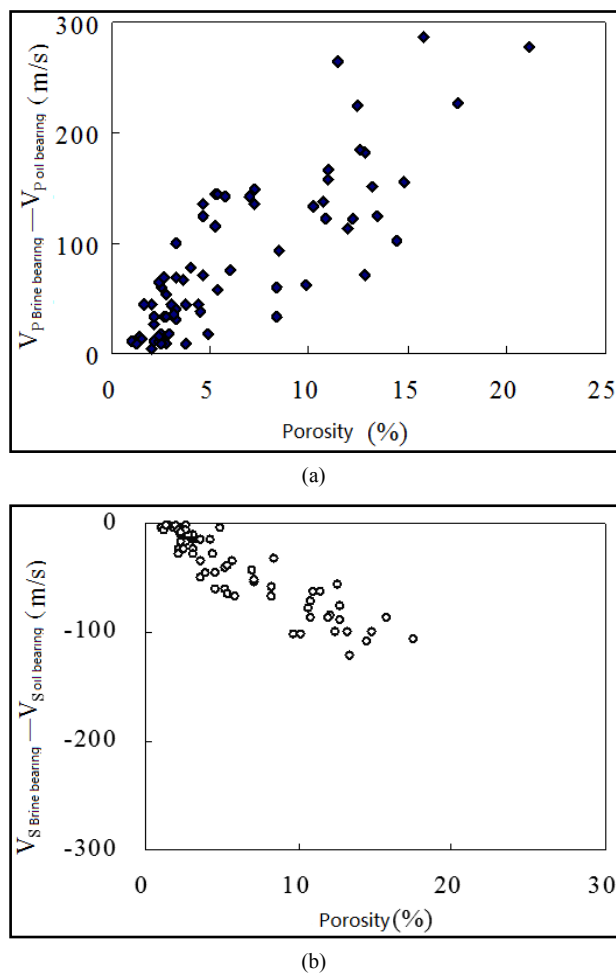

Figure 4. Difference in compressional wave (a) and Shear wave (b) Velocities between brine-bearing and oil-bearing one Versus Porosity.

reestablish the density logging curve.

- 4) The compressional and shear wave decrease when the porosity or the shale content increase, the acoustic velocity of tuffaceous rock-fragment sandstone has good negative linear relationship with the porosity and shale content. The influence of shale content on the acoustic velocity is only 1/5 - 1/10 of that of porosity, which may be related to the tuff shale in the samples. Therefore, when calculating the porosity of the reservoir in cretaceous of Haita, the influence of shale can be ignored.
- 5) The increase of water saturation will lead to the increase of compressional velocity and the slight decrease of shear wave velocity. The change of acoustic velocity is positive related to the porosity, but the largest change can't exceed 6%. Therefore, if the compressional and shear wave velocities obtained from the seismic and logging data has low uncertainty, it is possible to use the seismic and logging data to recognize the oil and gas reservoirs with good physical properties.
