Abstract

The calcination reaction of limestone is always accompanied by sintering of the calcined product. In addition, accelerated sintering rates and a reduced specific surface area are observed in the presence of steam and carbon dioxide. To simulate the change of surface area and the porosity of limestone samples in a simultaneous calcination and sintering process, a combined model based on both a sintering model and a calcination model is established. The calcination model, which predicts calcination conversion as a function of time, is based on the initial properties of the sorbent. The sintering model is according to the German and Munir model in which the main transport mechanism is supposed to be lattice diffusion. In a flow reactor, the surface area value and calcination rate of limestone in the presence of steam and CO₂ are also described by the combined model with modified parameters.

Keywords

Calcination, Sintering, Limestone, Combined Model

1. Introduction

Sintering refers to the changes in pore shape, pore shrinkage and the increase in grain size that CaO particles undergo during heating. The rate of CaO sintering increases at higher temperatures, as well as at higher partial pressures of carbon dioxide and steam vapor. The presence of impurities also increases the sintering rate. In general, higher temperatures are required to increase reaction rates, but because of the sintering process, the structure of the calcine is more likely to change.

Beruto *et al.* [1] found that the surface area of CaO produced from calcite crystals is constant at 116 m²/g when the calcite crystals are decomposed under vacuum at 686°C. The volume occupied by a CaO aggregate is 98% that of the original calcite crystal. Powell and Searcy [2] also obtained the same surface area value for CaO in another apparatus with good evacuation. Furthermore, Beruto *et al.* [3] noticed the influence of CO₂ pressure on sintering when they measured a surface area of 89 m²/g CaO from the decomposition of large crystals of calcite at 580°C when the evacuation was less complete because of low vacuum pump speed.

Large particles of limestone calcinated in a rotary kiln at 980°C normally resulted in surface areas of only 2 to 5 m²/g. Chan *et al.* [4] attained a surface area of 24.6 m²/g by calcining limestone particles in a TGA at 745°C.

Fennell *et al.* [5] obtained the largest surface area of 39 m²/g at 1023 K in the study of the effect of repeated cycles on sorbent activity. Sun *et al.* [6] also found a surface area of 36 m²/g using Strassburg limestone in a TGA at 850°C. The TGA generally employed for these studies is limited to samples with a relative large particle density due to poor dispersion in the sample holder. The low gas throughput of the sample imposes another severe limitation because it aggravates the effect of CO₂ on sintering.

There exists evidence that the sintering mechanism of CaO is fundamentally related to the mass transport. Borgwardt *et al.* [7] noticed that the product layer diffusivities for the sulfation of CaO of varying purity show higher values when the CaO is derived from limestones than when it comes from pure CaCO₃. Further more, the addition of small amounts of certain salts is found to enhance sulfation especially when added to presintered CaO. The ions in these salts, such as Li⁺, Na⁺, Cr³⁺ and Mo³⁺, when incorporated into a CaO lattice, produce defects that promote solid state diffusion. Similar effects of these foreign ions are observed on the sintering of CaO. By comparing the result of the CO₂ looping cycle performance of a limestone, Manovic *et al.* [8] believed that the presence of Na ions increases the diffusion of Ca ions and that this enhanced diffusion accelerates the gas-solid reaction. From SEM images, Manovic *et al.* also observed the pronounced sintering and the loss of surface area as a result of the presence of Na ions in the CaO powder. As a result, Borgwardt *et al.* [9] found that the activation energy for the sintering of pure CaO is greater than that for the impure material. Therefore, the observed effects are consistent with the hypothesis that diffusion through the product layer occurs by ionic transport and that the mechanism of sintering is related to the mechanism of product layer diffusion.

This paper describes a combined model, based on a sintering model from German and Munir [10] and a first-order calcination model from Borgwardt [11]. Supposing that the surface area of limestone varies linearly with the mole fraction of CaO in the sample in the absence of sintering, the simulation results during simultaneous calcination and sintering are shown at various reaction temperatures. In the presence of steam and CO₂, the German-Munir model is also used to simulate an isothermal sintering process. The combined model is beneficial to the understanding of the diffusion mechanism in calcination and sintering reaction with or without a catalyzed atmosphere.

2. Model Description

2.1. Calcination and Sintering Model

Beruto and Searcy [12] showed that the calcination rate per unit area of a flat crystal surface is constant at a given temperature and calcination rates for limestone have been presented as a first-order Arrhenius expression, thus

$$\frac{dw_{\text{CaCO}_3}}{dt} = -K_c A_{\text{CaCO}_3} \quad (1)$$

where w_{CaCO_3} is the mass of the undecomposed calcium carbonate, K_c is the rate constant of the calcination reaction, and A_{CaCO_3} is the surface area of the calcium carbonate. Assuming that the induction period of the calcination can be neglected [13], the calcination rate at time t is proportional to the BET surface area of the undecomposed CaCO₃, thus

$$A_{\text{CaCO}_3} = s_g w_{\text{CaCO}_3} \quad (2)$$

where s_g is the specific BET surface area of limestone per unit mass. The rate expression given by Equation (1) can be integrated as:

$$\int_1^{1-x} \frac{dw_{\text{CaCO}_3}}{w_{\text{CaCO}_3}} = -K_c s_g \int_0^t dt \quad (3)$$

This yields the following calcination model for small particles:

$$\ln(1-x) = -K_c s_g t \quad (4)$$

where x is fractional conversion of CaCO₃ to CaO. The rate constant for the surface reaction in the Borgwardt [13] model showed an independent trend with the type of stone and the particle size from 1 to 90 μm. The equation accurately fits the measured extent of calcination as a function of time. Thus, the model of Borgwardt is utilized in the following calculation.

German and Munir [10] proposed a model of the interparticle neck shape during sintering. The following generalized expression is derived for this process:

$$\left(\frac{S_0 - S}{S_0}\right)^\gamma = K_s t \quad (5)$$

where S_0 is the initial specific surface area, S is the specific surface at time t , and K_s is the sintering rate constant. The exponent γ has unique values for the different transport mechanisms. Using the German-Munir model, Borgwardt [9] compared the rate of the surface area reduction in CaO that was derived from limestone. The exponent γ in Equation (5) was estimated by fitting the widest range of ΔS values. Values of $\gamma = 2.7$ yielded the best fit with these data. Thus, the model of Borgwardt is utilized in the following calculation.

Assuming that the CO_2 effect and the sintering of the calcine can be omitted under the differential condition, the surface area during calcination can be expressed as:

$$S_{id} = S_k x + S_i \quad (6)$$

where S_{id} is the surface area supposing that no sintering happens, S_k is the surface area constant and S_i is the initial surface area of the limestone.

According to this model, the CaO product is divided into increments depending on the time interval in which each increment is formed. At the j th time interval, the CaO produced in the i th time interval experienced the sintering time of the j -ith interval. Equation (5) can thus be rewritten as:

$$S = S_{id} \left(1 - \left(K_s (t_j - t_i)\right)^{1/\gamma}\right) \quad (7)$$

where S_{id} is the initial specific surface area and can be determined according to Equation (6). The surface area of the CaO formed during the i th time interval can be calculated by Equation (7) at the end of the j th time interval. The surface area of the entire product and the overall specific surface area of the calcined particle are calculated as

$$S_{\text{CaO}} = \sum_{i=1}^{i=j} S_{i,j} z_i \quad (8)$$

$$S_s(x, t) = x S_{\text{CaO}} + (1 - x) S_{\text{CaCO}_3} \quad (9)$$

where $S_{i,j}$ is the specific surface area of the CaO formed in the i th time interval at the end of the j th time interval, z_i is the fraction of the total CaO formed in the i th time interval, S_{CaO} is the specific surface area of the CaO product and S_{CaCO_3} is the specific surface area of the CaCO_3 .

In a review of much previous research, Milne *et al.* [14] compared the surface area and porosity measurements for carbonate-derived CaO with differing degrees of sintering and varying calcination conditions and found that when the surface area S is plotted against the porosity, a linear regression of many of the data sets passes through the origin. The upper limit of the data is represented by a curve. The empirical formula is utilized in this combined model and the specific surface area along this curve is expressed as:

$$S = 84.94 \frac{\varepsilon}{1 - \varepsilon} \quad (10)$$

Equation (4) is utilized to evaluate the conversion change with time. With Equations (6)-(9), the value of S is determined. The resultant porosity is determined with Equation (10).

2.2. Sintering Model in the Presence of Steam and CO_2

The sintering process that occurs in N_2 can be described with two parameters of K_s and γ , one temperature dependent and the other mechanism dependent. In true flue gas, both steam and CO_2 accelerate the CaO sintering. Anderson *et al.* [15] found that the surface reduction of CaO is sensitive to water vapor and that the reduction is due to crystallite growth, not merely agglomeration and closure of pores. Beruto *et al.* [16] showed the catalytic effect of CO_2 by measurements of the surface area and porosity reduction in CaO below the equilibrium pressure of CaCO_3 decomposition. In the presence of steam and CO_2 , sintering is a process involving multiple transport

mechanisms, so Equation (5) can not be strictly applied. The rate constant K and γ both change with gas composition and temperature as more than one mechanism becomes effective. Because this is an empirical approach, the values of K and γ no longer have significance regarding the sintering mechanism.

The experiment results of Borgwardt [17] show that the parameter γ becomes dependent on temperature and partial pressure in the presence of steam and CO_2 .

The relationships between γ and the partial pressure of steam or CO_2 can separately be expressed as

$$\ln\gamma_{\text{H}_2\text{O}} = 0.00262T + (\ln P_{\text{H}_2\text{O}} - 1.39)/11.1 \quad (11)$$

$$\ln\gamma_{\text{CO}_2} = 0.0034T + (\ln P_{\text{CO}_2} - 1.948)/44.9 \quad (12)$$

The parameter γ in presence of steam and CO_2 is a function of temperature and the composition of the sintering atmosphere and can be expressed as

$$\gamma_{\text{H}_2\text{O}+\text{CO}_2} = 0.376(\gamma_{\text{H}_2\text{O}} + \gamma_{\text{CO}_2}) + 8.8 \quad (13)$$

The parameter K_s in atmospheres containing both steam and CO_2 is given by

$$\ln K_s = 1.485 + 0.558 \ln P_{\text{CO}_2} - 11660/T \quad (14)$$

Combining Equations (11)-(14) with Equation (5), an empirical model for S as a function of time is given.

3. Simulated Results of Models

Although there are a large number of calcine-sintering experiments, work on the simultaneous calcination and sintering process under the differential condition is scarce. In this paper, the rate constant K_c for the surface reaction in the calcination model is first determined by the experimental data from the flow reactor with 10 μm Fredonia limestone [13]. Second, the sintering rate constant K_s in the sintering model is acquired using the surface-area reduction curve in a particle size range of 2 to 20 μm using the same Fredonia limestone [9] because the effect of particle size on the sintering rate in this range can be omitted. The BET surface area of 10 μm Fredonia limestone is 0.86 m^2/g . The calcination and sintering activation energies are calculated separately by the rate constant point at the temperature range indicated. It should be noted that the surface area constant (S_k) must be determined accurately and uncertainties in S_k will significantly influence the surface area calculated. Because sintering occurs even at low temperatures during the calcination process, the value can not be obtained by BET measurement. Fredonia limestone with a particle diameter of 10 μm were calcined in the differential reactor at 700°C and a mean value of 104 m^2/g was used for all calculations involving the CaCO_3 derivative [9]. Thus, the surface area constant calculated by the combined model at 700°C is 107 m^2/g and this surface area constant is utilized in the combined model at various calcination temperatures. Supposing that the calcination reaction of Fredonia limestone is performed at 700°C - 1000°C, the predictions of the model at various reaction temperatures with a particle diameter of 10 μm is shown in **Figure 1** and the combined model parameters and the simulated results are listed in **Table 1**.

According to the calculation results of the combined model, the uppermost value of 104.2 m^2/g happened at 114.7 second for Fredonia limestone calcinated at 700°C. Even one minute later, the value of the surface area heated at 700°C is more than 104 m^2/g . The change in surface area after the calcination reaction is not significant, which is the reason that Borgwardt prepared the precalcined limestone sample at 700°C. When the calcination temperature is increased from 700°C to 1000°C, the period of complete calcination is reduced from 114.7 sec to 0.4 sec, which is shown in **Table 1**. However, the maximum surface area under various calcination temperatures does not change much before the temperature effect on sintering becomes significant in the ensuing period. **Figure 1** also shows that increasing the reaction temperature enhances the calcination rate and the sintering rate, which causes the surface area and the porosity of a limestone sample calcined at 1000°C to decrease to values of 78 m^2/g and 0.45, respectively, after a 60 sec reaction time.

In **Figure 2**, the calcination rate and surface area data reported by Bortz *et al.* [18] of 13 μm Marianna limestone calcined in a flow reactor at 1373 K are compared with the prediction of the model in the presence of steam and CO_2 . Because the initial surface area of Marianna limestone is not provided in the work of Bortz, the BET surface area of 0.86 m^2/g is assumed in this model. The parameter of K_c is obtained from the calcination rate in **Figure 2(a)**. The partial pressures of CO_2 and steam in the flue gas atmosphere are 7.5 kPa and 14 kPa, respec-

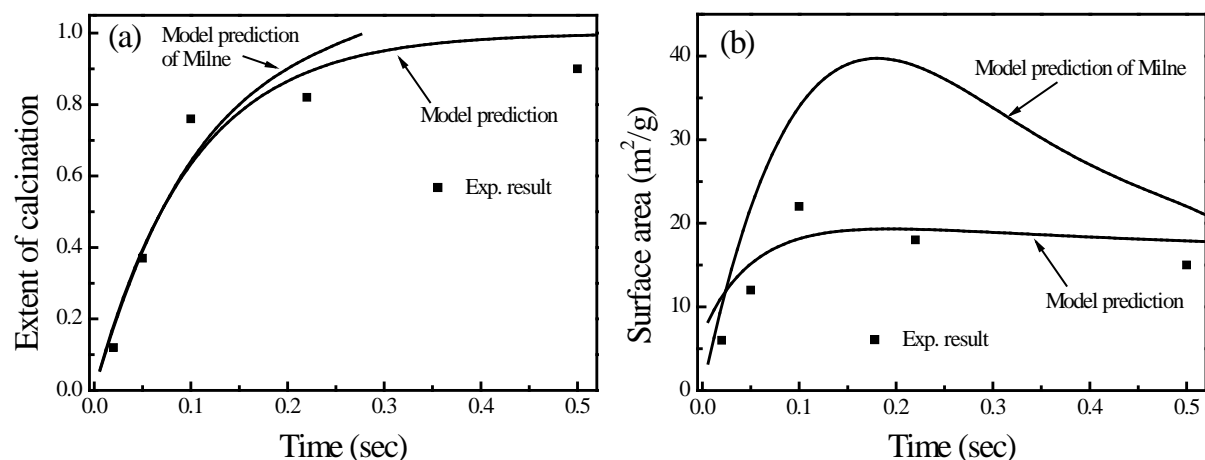

Figure 2. Model prediction for 13 μm Marianna limestone calcined at 1373 K in a flow reactor [18], (a) Extent of calcination, and (b) Surface area.

Table 1. Model parameters and simulated results.

T (°C)	K_c (g/m ² ·min)	K_s (1/t)	S_{Max} (m ² /g)	t (Sec)
700	3.8	0.000027	104.2	114.7
775	20.5	0.00024	103.7	20.8
860	120.5	0.002	103.3	3.5
925	500.5	0.0084	103.3	0.8
1000	1000.5	0.036	102.2	0.4

tively. The parameters γ and K_s , calculated with Equation (13) and Equation (14), are 45 and 0.02, respectively. **Figure 2(b)** shows a comparison between the predictions of the Milne model [14] and that of the model in this paper. Milne applied an empirical surface area expression to reflect the influence of steam and CO₂ and a prior knowledge of the asymptotic surface area as a function of temperature should be required. The sintering model of this paper in the presence of steam and CO₂ utilizes only the German-Munir model and the parameters of γ and K_s are obtained only according to the simulation formula provide by Borgwardt [17]. The model prediction is closer to the actual surface area of the 13 μm Marianna limestone. The experimental result and model simulation show that the surface area reduction is accelerated in the presence of steam and CO₂. The sintering activation energy in the presence of steam and CO₂ is 97 kJ/mol, calculated with the diffusion coefficient K_s ,

which is much less than the sintering activation energy in N₂. The increased sintering rate caused by steam and CO₂ is in accord with the expected effect of surface diffusion and grain boundary diffusion. Relative to the sintering rate of lattice diffusion, these two diffusions reduce the apparent sintering activation energy and increase the diffusivity. According to the combined model, at 1100°C the surface area of Fredonia limestone produces the maximum observed value of 102.2 m²/g at 0.08 sec in N₂. However, the result of the model in the presence of steam and CO₂ suggests an approximate peak surface area of 18.5 m²/g at 0.15 sec, which is shown in **Figure 2(b)**. A shift of the primary sintering mechanism from slow lattice diffusion to the faster mechanism would agree with the effects apparent from this comparison.

4. Conclusion

The German-Munir model not only can be used to correlate the kinetics of the CaO surface area reduction in inert atmospheres but also can be modified to empirically account for the effects of steam and CO₂. The surface area value and porosity of limestone samples in simultaneous calcination and sintering process is determined by a combined model. The surface area reduction during sintering suggests that besides lattice diffusion both surface diffusion and grain boundary mechanisms are more evident in the presence of steam and CO₂.

Notation

A_{CaCO_3}	Surface area of calcium carbonate, m ²
K_c	Rate constant for surface area, g/m ² ·min
K_s	Sintering rate constant in an inert atmosphere, t ⁻¹
S	Specific surface area at time t , m ² /g
S_0	Initial specific surface area of CaO following decomposition of its precursor, m ² /g
S_{CaO}	Specific surface area of CaO product, m ² /g
S_{CaCO_3}	Specific surface area of CaCO ₃ , m ² /g
S_k	Surface area constant without the CO ₂ effect on sintering, m ² /g
S_i	Initial surface area of limestone, m ² /g
S_{id}	Surface area supposing that no sintering happens, m ² /g
$S_{i,j}$	Specific surface area of CaO formed in the i th time interval at the end of the j th time interval, m ² /g
S_s	Overall specific surface area of the particle, m ² /g
s_g	Specific BET surface area of limestone, m ² /g
t	Time
t_i	i th time interval
t_j	j th time interval
w_{CaCO_3}	Undecomposed calcium carbonate in sample, g
x	Fractional conversion of CaCO ₃ to CaO
z_i	Fraction of total CaO formed in the i th time interval

Greek letters

γ	Mechanism-dependent exponent
γ_{CO_2}	Mechanism-dependent exponent in atmosphere of N ₂ containing CO ₂
γ_{H_2O}	Mechanism-dependent exponent in atmosphere of N ₂ containing H ₂ O
$\gamma_{H_2O + CO_2}$	Mechanism-dependent exponent in atmosphere of N ₂ containing H ₂ O and CO ₂
ε	Porosity of sample
