Abstract

Background: Laparoscopic distal gastrectomy (LDG) for gastric adenocarcinoma (GA) is gaining more acceptances worldwide. Its results are still controversial. This study aimed to assess short term outcomes of LDG and compare it to the standard open distal gastrectomy. **Patients and Methods:** 27 patients with GA of the distal 2/3 of the stomach were included and divided into 2 groups; Group A: 15 patients submitted to open distal gastrectomy with D2 lymph node (LN) dissection, and Group B: 12 patients submitted to LDG with D2 LN dissection. **Results:** The median age was 54 and 54.3 years in group A and B respectively. The median operative time was 118.7 and 210.2 minutes in group A and B respectively. The median safety margin was 6.52 and 5.7 cm in group A and B respectively while the median number of excised LN was 24.2 and 21.4 in group A and B respectively. One patient in group B had intra-operative bleeding that was controlled laparoscopically. No conversion to open surgery needed in group B. The median number of narcotic doses was 5.9 and 4.25 in group A and B respectively. The median length of hospital stay was 7.2 days in group A and 7.3 days in group B. Three patients in group A and 2 patients in group B had postoperative complications and all were treated successfully conservatively. **Conclusion:** LDG with D2 LN dissection is oncologically safe with short-term outcomes comparable to those of the open surgery. Gaining more surgeons' experience is necessary to improve these results.

Cancer Stomach, Distal Gastrectomy, Laparoscopic Resection

1. Introduction

Gastric adenocarcinoma (GA) is a leading cause of cancer-related deaths all over the world [1]. Surgical resection of the non-metastatic GA is the treatment of choice as it gives the patient acceptable long-term survival rates [2]. According to the Japanese Gastric Cancer Association treatment guidelines, the standard treatment of advanced GA and early GA with clinically negative nodes (cN0) involving the distal two thirds of the stomach is distal gastrectomy with D2 lymph node (LN) dissection [3]. This operation was performed laparoscopically for the first time by Seijo Kitano in 1994 [4]. Since that time, laparoscopic gastrectomy (LG) for early GA has gained increasing popularity in different countries as it doesn't only offer the patient an excellent chance for cure, but also, all the advantages of minimally invasive surgery including less postoperative pain, shorter hospital stay, faster recovery and better quality of life [5] [6] [7]. However, laparoscopic gastrectomy for GA has its own limitations. It is considered by many surgeons a complicated time consuming technique that requires advanced skills [8] [9]. The aim of this study was to report the short-term outcomes of laparoscopic distal gastrectomy (LDG) with D2 LN dissection in comparison to those of the standard open approach in the treatment of GA involving the distal two thirds of the stomach.

2. Patients and Methods

2.1. Study Design

This study was conducted during the period from May 2013 to August 2016. It included 27 patients presented by GA to General Surgery Department, Tanta University Hospital, Egypt and Hamad General Hospital, Hamad Medical Corporation, Qatar. All the patients were submitted to full history taking and thorough clinical examination. All the patients had upper gastrointestinal endoscopy and the gastric cancer was biopsied. Histopathological examination confirmed the diagnosis of GA in all patients. Computed tomography (CT) scans of the chest, abdomen and pelvis were obtained to assess the local extent and to exclude distant spread of the tumor. When distant spread was suspected on CT scan, positron emission tomography/CT (PET/CT) was performed before proceeding to curative resection. The cT and cN stage of the tumor were assessed using endoscopic ultrasonography (EUA) in all patients. Baseline carcinoembryonic antigen (CEA) level was done for all patients.

Patients with early (cT1) and locally advanced (cT2, cT3) GA involving the distal two thirds of the stomach without distant metastasis (cM0) were included in the study. Exclusion criteria included cT4 tumors, cM1 tumors, recurrent tumors, tumors located in the proximal third of the stomach and other types of gastric cancers (lymphoma, carcinoid and gastrointestinal stromal tumors). Patients with previous upper abdominal surgery and those with American Society of Anaesthesiologists (ASA) score more than 3, were also excluded.

All the cases were discussed in a multi-disciplinary team meeting and the de-

cision was surgical resection for all of them. An informed written consent was obtained from every patient and the study design was approved by the research and ethical committees.

Patients fulfilling selection criteria were divided randomly into 2 groups using the closed envelop method:

- Group A: included 15 patients. In this group, surgery started with staging laparoscopy and when intra-abdominal disease spread was excluded, the surgeon proceeded to midline laparotomy with distal gastrectomy and D2 LN dissection.
- Group B: included 12 patients who were submitted to LDG with D2 LN dissection after exclusion of distant intra-abdominal tumor spread.

2.2. Surgical Technique

All patients received prophylactic antibiotics in the form of Ceftriaxone 2 gm and Metronidazole 500 mg intravenously on anesthesia induction. In group (B), the patient was placed in Lloyd Davies position, the surgeon stood between the patients, legs with the assistant on the left side and the camera holder on the right side. A thirty degree 10-mm telescope was inserted through a 10-mm port placed 1-cm below the umbilicus. Two 12-mm trocars were inserted 5-cm below the right and left costal margin in the anterior axillary line for the surgeon's hands. A 5-mm trocar is then inserted in the left mid-axillary line 2-cm below the costal margin for the assistant. Another 5-mm trocar is inserted 3 cm below the xiphoid process to the left of the midline for liver retraction.

The procedure started in all the cases by staging laparoscopy to exclude intra-abdominal spread [Figure 1]. Then, the greater omentum was divided along the avascular plane between it and the transverse colon with dissection of the LN along the greater curvature of the stomach (level 4d). The left gastroepiploic vessels were exposed and divided close to the splenic hilum to ensure removal of the LN related to them (level 4sb). The right gastroepiploic vessels were then exposed and divided in a similar way with removal of the infra-pyloric LN (level 6) [Figure 2]. While the gastric antrum is retracted anteriorly, dissection continues in the plane between the pylorus and 1st part of the duodenum anteriorly and the pancreas posteriorly starting from below upwards. The upper margin of the 1st part of the duodenum and pylorus were dissected dividing the supraduodenal vessels. The right gastric artery is divided at its origin from the hepatic artery proper sweeping the suprapyloric LN (level 5) downwards towards the specimen. The lesser omentum was divided close to its hepatic attachment and the stomach retracted downward and to the left exposing the coeliac trunk and its branches. The common hepatic LN (level 8a) were dissected, the left gastric vessels were dissected and divided with removal of the surrounding LN (level 7) [Figure 3] and the LN around the celiac artery (level 9). The lymph nodes along the proximal lesser curvature were dissected off the gastric wall starting from the cardia downwards till the planned level of gastric division. The 1st part of the duodenum was divided using an endo-GIA stapler [Figure 4]. Then, proximal

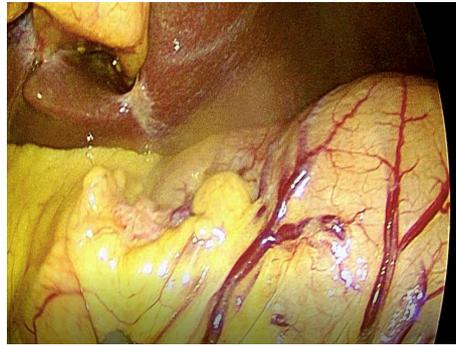

Figure 1. Tumour of the distal third of the stomach.

Figure 2. Clipping of right gastro-epiploic vessels.

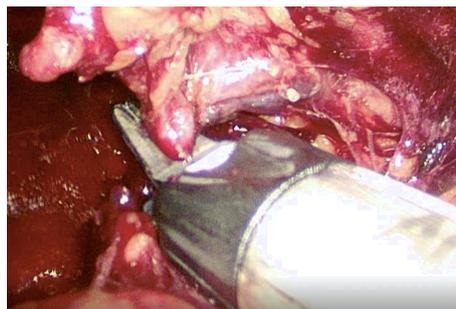

Figure 3. Clipping of left gastric vessels.

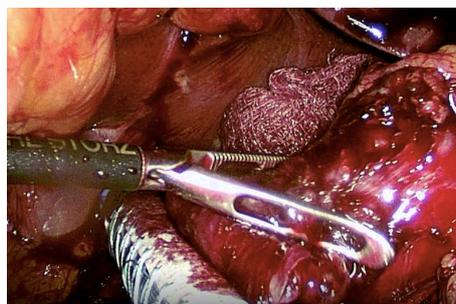

Figure 4. Stapling of the distal end of the stomach.

gastric division was done, at least, 4 cm proximal to the gross margin of the tumour by repeated firings of the endo-GIA stapler [Figure 5]. The excised specimen was placed in an endo-bag to be retrieved from the umbilical port at the end of the procedure. Reconstruction was performed in the form of a Roux-En-Y gastrojejunostomy using endo-GIA stapler. Two drains were placed in the

Figure 5. The gastric pouch after complete resection.

hepato-renal space and the lesser sac and the wounds were closed in layers.

In group (A), the abdomen was accessed through a midline incision extending from the Xiphoid process to few centimeters below the umbilicus. The conduct of the procedure is the same as in the laparoscopic approach.

In both groups, the monopolar diathermy, the Harmonic™ Ultrasonic Shear (Johnson and Johnson Medical, Ethicon, Cincinnati, OH, USA) or the Force-Traid™ (Vallelab, Covidien, Minneapolis, USA) were used for dissection and haemostasis. The operative time, the intra-operative blood loss and any intra-operative complications were recorded.

2.3. Postoperative Care

Post-operatively, patients were put on Ceftriaxone 1 gm IV/24 hours and Metronidazole 500 mg IV/8 hours for 24 hours. Postoperative analgesia was provided in the form of Paracetamol 1 gm IV/6 hours and Morphine 5 mg SC/6 hours on-demand according to the severity of pain. After return of normal gastrointestinal motility, the nasogastric tube was removed and the patients were allowed oral intake with clear fluids increased gradually to full diet over the next few days. The abdominal drain was removed when patients tolerated clear oral fluids provided there was no leak. Patients were discharged home when they were self-dependent, with no or mild pain, tolerated oral intake with no surgical complications.

Postoperative pain severity was assessed using the Visual Analogue Scale (VAS) at 24 hours, 3 and 7 days after the surgery. Postoperative data collected included the severity of postoperative pain as assessed by the VAS, the number of narcotic analgesic injections needed on demand, the time of return of postoperative bowel motility, the postoperative complications, and the length of postoperative hospital stay.

2.4. Statistical Analysis

Data were tabulated and analyzed using SPSS Statistics software package version 20. Metric and ordinal data were presented as range and median while nominal data were expressed as percentage. Mann-Whitney test was used to compare metric data while two sample *t*-test was used to compare ordinal data. *P* value of less than 0.05 was considered statistically significant.

3. Results

3.1. Demographic

This study included two matched groups of patients; Group A included 15 patients submitted to open distal gastrectomy and D2 LN dissection and Group B included 12 patients submitted to LDG and D2 LN dissection. The age of the patients in group A ranged from 41 to 67 years with a median of 54 years and male: female ratio of 9:6. In group B, the age ranged from 47 to 60 years with a median of 54.3 years and male: female ratio of 7:5. Associated co-morbidities and the ASA class of patients in the 2 groups were shown in **Table 1**.

3.2. Operative Data

The operative time in group A ranged from 100 to 143 minutes with a median of 118.7 minutes. The intra-operative blood loss ranged from 120 to 180 ml with a median of 152.2 ml. The length of the safety margin ranged from 5.6 to 7.8 with a median of 6.52 cm from the proximal edge of gross tumor. The number of dissected LNs ranged from 18 to 33 with a median of 24.2 LNs. No operative complications were recorded. In group B, the operative time ranged from 185 to 255 minutes with a median of 210.2 minutes. The intra-operative blood loss ranged from 66 to 95 ml with a median of 78.3 ml. The length of the safety margin ranged from 5.2 to 7.1 cm with a median of 5.7 cm. The number of dissected LNs ranged between 17 and 31 with a median of 21.4 LNs. No conversion to laparotomy was needed. One patient developed intraoperative bleeding from the right gastric artery during lesser sac dissection. It was successfully controlled by vascular clips. The differences between the 2 groups in the median operative time and the median intra-operative blood loss were statistically significant

Table 1. Pre-operative patients, data.

Variable	Group A (No. = 15)		Group B (No. = 12)		P value
	No	%	No	%

• II	8	53.3	6	50	0.171
• III	4	26.6	3	25	0.094

(118.7 vs 210.2 minutes; $P < 0.01$ and 152.2 vs 78.3 ml; $P < 0.01$ respectively). On the other hand, the differences between the two groups in the median number of intraoperative complication, tumor grade, pT stage, tumor size, median length of the least safety margin and median number of dissected LNs were statistically insignificant (**Table 2, Table 3**).

3.3. Post-Operative Outcomes

Post-operatively, the number of narcotic doses ranged from 5 - 11 doses with a median of 5.9 doses in group A while in group B, the number of narcotic doses ranged from 4 - 6 doses with a median of 4.25 doses. The median VAS scale at 1, 3, and 7 days was 6.6, 4.7, and 2.9 for group A, and 5, 3.8, and 2.2 for group B respectively. The time to pass first flatus ranged from 2 - 4 days with a median of 2.7 days in group A while in group B, it ranged from 1 - 3 days with a median of 2.1 days. The length of hospital stay ranged from 6 - 10 days with a median of 7.2 days in group A while it ranged from 6 - 13 days with a median of 7.3 days in group B. The differences between the 2 groups in the median number of analgesic injections, median VAS at 3 and 7 postoperative days were statistically significant. ($P = 0.04, 0.04,$ and 0.035 respectively). On the other hand, the difference between the two groups in the median length of hospital stay was found statistically insignificant (7.2 vs 7.3 days; $P = 0.86$) (**Table 4**).

Post-operative complications in group A included 2 patients (13.3%) with wound infection and 1 patient (6.7%) with pneumonia. In group B, 1 patient (8.3%) developed pancreatitis in the third post-operative day that was treated conservatively and the patient was discharged on eighth post-operative day. Another patient (8.3%) developed post-operative leakage on day 6 from the site of gastro-jejunostomy as proven by the CT scan. Since this patient had low output leakage with no intra-abdominal collections, he was treated conservatively by ICU admission, total parenteral nutrition and supportive care. The fistula closed spontaneously with no need for further surgical intervention. The difference between the two groups in the median number of postoperative complications was statistically insignificant (3/15 vs 2/12; $P = 0.77$) (**Table 5**).

3.4. Follow up Results

All the patients were followed in the Surgical Outpatient Clinic 2 weeks post-operatively and they were referred to Oncology Department to receive their adjuvant therapy.

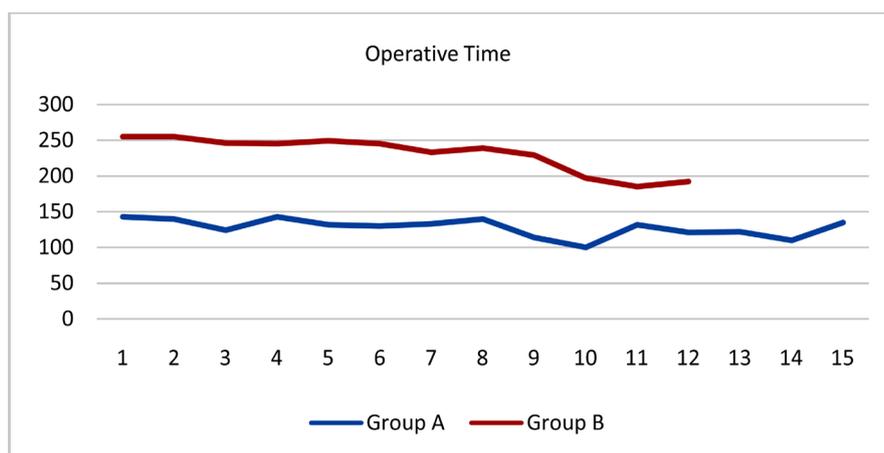

Three months, 6 months, 1 year, & 2 years follow up to all patients was done, and showed local recurrence in one patient (1 year post-operatively) and lung metastasis in another patient (6 months post-operatively). Both patients were in group B and were treated by palliative chemo-irradiation.

4. Discussion

In this study, we report the short term outcomes and our early experience in

Table 2. Operative findings.

LDG for GA and compare these results with the standard open technique. The study population included two matched groups of patients with no statistically significant differences between the 2 groups in terms of age, sex, comorbid conditions, ASA class and tumor stage (**Table 1**).

In all patients included in this study, we performed staging laparoscopy before proceeding to definitive surgical resection because we think that staging laparoscopy is a crucial step for detection of occult metastases undetectable on preoperative work-up, thus, avoiding patients with these metastases in the open group unnecessary laparotomies [10] [11].

We excluded patients with previous upper abdominal surgeries because the underlying adhesions may increase the difficulty of the laparoscopy, affect the safety of laparoscopic dissection, and may increase the incidence of conversion to open surgery. Patients with tumors in the upper third of the stomach were also excluded as these patients will need more extensive resection in the form of subtotal or total gastrectomy and may need esophageal resection; techniques that need more complex steps during laparoscopy [12] [13]. For the same reason, we excluded patients with T4 tumors that invade the serosa and/or the surrounding structures [14].

We adopted the rules of proper oncological resection of GA that include a

minimum safety margin of 4 cm and D2 LN dissection [14]. The LN dissection in GA should include the perigastric LN (D1) and the LN along the named branches of the celiac artery (D2) with excision of at least 15 LN [15] [16]. Several studies including randomized controlled trial, systematic reviews and meta-analyses, both in Asian and western countries, have shown that D2 LN dissection in advanced GA is associated with improved survival, lower rates of recurrence, and lower rates of cancer-related deaths if compared to D1 dissection [17]-[24]. Nowadays, D2 procedure is recommended as the standard procedure by the Japanese, Korean, German, British, Italian, European Society for Medical Oncology (ESMO) and the joint ESMO-ESSO (European Society of Surgical Oncology)-ESTRO (European Society of Radiotherapy and Oncology) guidelines. Moreover, recently National Comprehensive Cancer Network (NCCN) recommends a D1+ or a modified D2 also in the United States [25].

Although laparoscopic surgery provides the patients with many advantages including smaller incisions, less postoperative pain, faster recovery and better cosmesis, the implementation of this technique in the field of gastric cancer surgery is not widely practiced because LG is technically demanding and needs extensive experience both in laparoscopic and oncologic surgery [26] [27]. Thus, till now, it is currently a matter for debate if LG with D2 lymphadenectomy should represent an appropriate treatment for advanced gastric cancer. Challenging technical issues could be represented by large-size tumors or tumors that require multiorgan resection [28] [29].

The main outcome of this study shows that LDG with D2 LN dissection for distal GA is safe and oncologically sound. Moreover, it provides the patients all the advantages of laparoscopic surgery including reduction of the postoperative pain and the duration of postoperative ileus in comparison to the open approach. These results agree with the results of many other studies [3] [30] [31]. Although the length of hospital stay in our study was longer in the open surgery group, the difference did not reach a statistical significance (7.2 vs 7.3 days; $P = 0.86$). This difference can be attributed to the prolonged length of stay for the 2 patients in group B who developed postoperative leakage and pancreatitis and to the small number of patients in our study.

In terms of operative findings, our study showed that, when compared with open surgery, laparoscopy produced significant reduction of median intraoperative blood loss (152.2 vs 78.3 ml; $p < 0.01$), although it was associated with a significant increase in the median operative time (118.7 vs 210.2 minutes; $p < 0.01$). Nevertheless, both groups did not show significant differences in the median number of the dissected LN or the median safety margin of excision as shown in **Table 3**. Our results agree with those of many other studies showing longer operative time and less blood loss for the laparoscopic groups [6] [32] [33] with no difference between laparoscopic and open gastrectomy regarding the least margin of excision and the number of dissected LN [27] [34].

In the open surgery group, 3 patients developed postoperative complications

which included 2 superficial wound infections and 1 pneumonia. In the laparoscopic surgery group, 2 patients developed complications postoperatively which included postoperative pancreatitis in 1 patient and postoperative leakage in the other. The difference between the two groups was statistically insignificant (P value = 0.77). While our results are supported by those of several authors [7] [21] [31], Zeng *et al.* [12] and Vinuela *et al.* [35] showed significantly fewer postoperative complications in the laparoscopic group when compared to the open group.

5. Conclusion

In conclusion, based on the results of this study, LDG with D2 LN dissection performed for GA is safe, oncologically sound with short-term outcomes comparable to those of open surgery. Moreover, it provides the patients all the advantages of minimally invasive surgery. However, a study on a larger number of patients with a longer follow-up is needed for more valid results. Also, we believe that increasing the experience of the operating surgeons will result in better outcomes.

Submit or recommend next manuscript to SCIRP and we will provide best service for you:

Accepting pre-submission inquiries through Email, Facebook, LinkedIn, Twitter, etc.

A wide selection of journals (inclusive of 9 subjects, more than 200 journals)

Providing 24-hour high-quality service

User-friendly online submission system

Fair and swift peer-review system

Efficient typesetting and proofreading procedure

Display of the result of downloads and visits, as well as the number of cited articles

Maximum dissemination of your research work

Submit your manuscript at: <http://papersubmission.scirp.org/>

Or contact ss@scirp.org
