Abstract

The contribution of benthic foraminifera to sediment bioturbation has widely been overlooked despite their huge abundance in intertidal soft sediments. In this preliminary study, we specifically chose to focus on two key species of benthic foraminifera in temperate intertidal mudflats, *Quinqueloculina seminula* and *Ammonia tepida*, and first experimentally investigated their individual movements at the sediment surface. We subsequently derived from these observations the individual-level surface sediment reworking rates, and used the actual abundance of these species to extrapolate these rates at the population level. Individual surface sediment reworking rates $SSRR_i$ ranged between 0.13 and 0.32 $\text{cm}^2 \cdot \text{ind}^{-1} \cdot \text{day}^{-1}$ for *Q. seminula*, and between 0.12 and 0.28 $\text{cm}^2 \cdot \text{ind}^{-1} \cdot \text{day}^{-1}$ for *A. tepida*. Population-level surface sediment reworking rates were subsequently estimated as ranging between 11,484 and 28,710 $\text{cm}^2 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ for *Q. seminula* and 27,876 and 65,044 $\text{cm}^2 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ for *A. tepida*. Noticeably, these reworking rates are comparable to, and eventually even higher than, the rates reported in the literature for populations of intertidal macro-invertebrates, such as the annelid polychaete *Melinna palmata* and the bivalve *Abra ovata*. Taken together these results suggest that despite their minute size intertidal benthic foraminifera are, thanks to their abundance, non-negligible contributors to the reworking of surface sediment, and may then play an unanticipated role in the benthic ecosystem functioning, through e.g. the enhancement of fluxes at the sediment-water interface.

Keywords

Benthic Foraminifera, Bioturbation, Surface Sediment Reworking Rate,

1. Introduction

Benthic fauna typically influences the structure and function of soft-sediment benthic ecosystems through bioturbation, that is the biogenic modification of sediments through particle reworking and burrow ventilation; see [1] for a review. For instance, bioturbation by infaunal macrobenthos has been shown to influence sediment granulometry, oxygen, pH and redox gradients [1], bacterial metabolic activity and community composition, and ultimately carbon and nitrogen cycling [2]. Noticeably, the contribution of meiofauna to sediment bioturbation has been far less studied [3] [4] [5] [6] [7], and barely considered in an attempt to estimate community bioturbation potential based on a review of 1033 benthic invertebrate species from the northwest European continental shelf [8]. A recent review [9] even showed that most publications on the role of benthic meiofauna dealt with nematodes and harpacticoid copepods. Despite their high abundance (they can represent up to 50% of the eukaryotic biomass; [10]) and their acknowledged contributions to global calcium carbonate production [11] and both carbon and nitrogen cycles [12] [13], the role of benthic foraminifera on fluxes at the sediment-water interface in general and bioturbation in particular is still to be quantified.

A few typical features of the ecology of benthic foraminifera such as cyst building [14] and locomotion [15] [16] are, however, likely leading to displace sediment particles. Specifically, foraminiferal movements typically lead to the creation of intense networks of surface trails [17]. These trails may enhance the erodibility of mudflat sediments as previously shown for benthic macrofauna [18]. Movements of benthic foraminifera are, however, not restricted to the sediment surface [19]. Benthic foraminifera are able to migrate down through the sediment, up to a depth of 4 cm for *Quinqueloculina impressa* [17]. This process leads to the construction of biogenic structures, such as networks of galleries for *Q. impressa* [17] and cavities for *Elphidium excavatum clavatum* [20] [21]. These biogenic structures contribute to a better oxygenation of the surface layer [22] and ultimately determine the fluxes of both particulate and dissolved materials at the sediment-water interface as in benthic macrofauna [1]. However, to the best of our knowledge only one deep-sea study estimated the bioturbation rate of a population of benthic foraminifera as $0.2 \text{ cm}^2\cdot\text{year}^{-1}$ [23]. This rate is noticeably comparable to the rates reported for a population of benthic macrofauna in a coastal lagoon, *i.e.* $0.5 \text{ cm}^2\cdot\text{year}^{-1}$ [24]. Taken together, these observations suggest that benthic foraminifera may have the ability to significantly contribute to sediment reworking. This is, however, still an open question as only one study quantified bioturbation by benthic foraminifera [23].

In this context, as a first step in assessing the ability of benthic foraminifera to

contribute to sediment reworking, we followed the surface image analysis method initially developed to quantify macrofauna surface sediment reworking rates [25]. Among the range of methods available to assess sediment reworking rates (see review in [26]), the surface image analysis method appeared to be the most appropriate one for benthic foraminifera at this stage since 1) little is still known about reworking activities by benthic foraminifera, 2) their contribution to bioturbation is likely to occur during locomotion, and 3) they are described as mostly living at the sediment-water interface. The objective of this preliminary study is to fill the knowledge gap related to the potential role played by benthic foraminifera in sediment reworking through quantitative laboratory assessment of the surface sediment reworking rates of two key foraminiferal species of temperate intertidal mudflats [27] [28], *i.e.* *Ammonia tepida* and *Quinqueloculina seminula*. To further assess the relevance of these reworking rates, we further discussed them in the general context of the reworking rates reported for macrofaunal species typical of soft sediment ecosystems.

2. Material and Methods

2.1. Sample Collection and Preservation

Sediment samples of the 0 - 1 cm layer were collected in triplicates using a core device (inner diameter: 8.6 cm) on two French intertidal mudflats, Saint-Vaast-La-Hougue (49°26'31.3"N, 0°16'25.2"E) and the Seine estuary (49°34'38.6"N, 1°16'38.8"W) in order to quantify abundances of *Quinqueloculina seminula* and *Ammonia tepida*. They were subsequently preserved in a mixture of 70% ethanol and Rose Bengal (2 g·l⁻¹) to separate living from dead specimens. Living foraminifera were collected by gently scraping off the sediment surface, maintained in a portable isotherm container at ambient temperature (22°C) and transported to the laboratory.

2.2. Sample Processing for the Abundance of Target Species

Replicates were washed through a 63 µm mesh, and the fraction > 63 µm was dried at 50°C. After drying, tests were concentrated by heavy liquid flotation using carbon tetrachloride (CCl₄). A total number of living foraminifera of 250 specimens per replicate were counted to have a representative assessment of their actual abundance [29]. Abundances (mean ± SD ind·cm⁻²) of *Ammonia tepida* in the Seine estuary and *Quinqueloculina seminula* in Saint-Vaast-La-Hougue were then estimated.

2.3. Experimental Set-Up and Behavioural Observations

The motion behaviour of *Quinqueloculina seminula* and *Ammonia tepida* was investigated in glass Petri dishes (7.5 cm in diameter) filled with a thin (ca. 5 mm) layer of *in situ* azoic (*i.e.* frozen at -20°C) sediment overlaid with *in situ* seawater (S = 32 PSU) to a height of 5 mm. All experiments were conducted under homogenous dim light conditions (450 lux; Light Probe Meter™ 403125,

Extech Instruments, Nashua, USA) in a temperature-controlled room at 22°C, a temperature representative of the conditions experienced *in situ* by these species at the time of sampling. Prior to individual collection, the fraction > 63 µm was kept in a temperature-controlled room at 22°C overnight. *Q. seminula* and *A. tepida* individuals were in the size range 400 - 500 µm and 300 - 400 µm, respectively. Respectively 14 and 15 distinct *Q. seminula* and *A. tepida* individuals were used in the behavioural experiments. Prior to each experiment, living individuals were carefully sorted under a stereomicroscope with a brush, and immediately transferred to the experimental Petri dish, where they were allowed to acclimatize for 5 min.

Individual activity was monitored using an automated acquisition system composed of a digital camera (Nikon J5 mounted with a Nikkor VR 10 - 30 mm lens) following the method described by Hollertz & Duchêne (2001) [25]. The position of each individual was subsequently recorded every 10 min for 24 hours, after which the (x, y) coordinates were manually extracted from the resulting 144 images using GraphClick (Arizona Software), and used to characterise the path travelled by each individual [15]. All experiments were conducted under continuous light and immersion conditions to avoid any behavioural bias that may relate to endogenous diel and/or tidal rhythms [15].

Test-length (L), total distance travelled (d) and the duration of the experiment t (*i.e.* 24 h) were used to calculate the individual surface sediment reworking rate $SSRR_i$ ($\text{cm}^2 \cdot \text{ind}^{-1} \cdot \text{d}^{-1}$) following Maire *et al.* (2008) [26] as $SSRR_i = dL/t$. *In situ* abundances of *Quinqueloculina seminula* and *Ammonia tepida* were subsequently used to scale the individual $SSRR_i$ up to a surface unit of 1 m² as a population-level surface sediment reworking rate $SSRR_p$ ($\text{cm}^2 \cdot \text{m}^{-2} \cdot \text{d}^{-1}$; [30] [31] [32]).

3. Results

Both *Quinqueloculina seminula* and *Ammonia tepida* drastically modified the initially smooth and undisturbed sediment surface (**Figure 1(A)**) where they typically created intense networks of sinuous trails surrounded by a fluffy layer of sediment (**Figure 1(B)**). These trails were typically as wide as the specimens test length L (*i.e.* 400 - 500 µm and 300 - 400 µm for *Q. seminula* and *A. tepida*, respectively), and the distance travelled in 24 h d ranged from 31.9 to 63.8 mm for

Figure 1. Archetypical example of the reworking of sediment surface by *Quinqueloculina seminula* over a period of 24 hours ((A): t_0 ; (B): t_{0+24h}).

Q. seminula and from 40.4 to 70.7 mm for *A. tepida*.

Individual surface sediment reworking rates $SSRR_i$ ranged between 0.13 and 0.32 $\text{cm}^2 \cdot \text{ind}^{-1} \cdot \text{day}^{-1}$ in *Quinqueloculina seminula* (Table 1). These rates were similar for *Ammonia tepida* with a minimum of 0.12 $\text{cm}^2 \cdot \text{ind}^{-1} \cdot \text{day}^{-1}$ and a maximum of 0.28 $\text{cm}^2 \cdot \text{ind}^{-1} \cdot \text{day}^{-1}$ (Table 1). Given the observed abundance of *Q. seminula* ($9 \pm 3 \text{ ind cm}^{-2}$; mean \pm SD) and *A. tepida* ($23 \pm 4 \text{ ind cm}^{-2}$), population surface sediment reworking rates $SSRR_p$ were subsequently estimated as ranging between 11,484 and 28,710 $\text{cm}^2 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ for *Q. seminula* and 27,876 and 65,044 $\text{cm}^2 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ for *A. tepida* (Figure 2).

4. Discussion

This study suggests that the intertidal foraminifera *Quinqueloculina seminula* and *Ammonia tepida* may drastically modify surface sediment. Specifically, the surface crawling activities (Figure 1(B)) reported here for *Q. seminula* and *A. tepida* resemble those of the gastropod *Peringia ulvae*, that involve both sediment reworking and the creation of a fluffy layer of sediment around the tracks [18]. Fluffy layers are disconnected from the surface matrix, decrease sediment cohesiveness, hence increase sediment erodibility [33]. Though this may be speculative, sediment reworking related to *Q. seminula* and *A. tepida* movements may also contribute to increase sediment erodibility. This modification of the surface sediment physical properties may subsequently enhance the benthic-pelagic coupling through increased resuspension of both sediment and microphytobenthos in the

Table 1. Minimum (Min) and maximum (Max) individual surface sediment reworking rate $SSRR_i$ ($\text{cm}^2 \cdot \text{ind}^{-1} \cdot \text{d}^{-1}$) and abundance ($\text{ind} \cdot \text{m}^{-2}$) of *Quinqueloculina seminula* and *Ammonia tepida*, sampled from intertidal mudflats located in Saint-Vaast-La-Hougue and the Seine estuary, respectively.

	Min	Max	Abundance
<i>Quinqueloculina seminula</i>	0.13	0.32	90,000
<i>Ammonia tepida</i>	0.12	0.28	230,000

Figure 2. Minimum and maximum population-level surface sediment reworking rate $SSRR_p$ ($\text{cm}^2 \cdot \text{m}^{-2} \cdot \text{d}^{-1}$) of the two studied foraminiferal species, *Quinqueloculina seminula* and *Ammonia tepida*.

water column [18]. Note that the population-level surface sediment reworking rates $SSRR_p$ estimated here are likely to be conservative estimates as other putative processes involved in sediment reworking (e.g. feeding activities and cyst building) have not been considered. In addition, because we restricted our experimental approach to large foraminifera (*i.e.* 400 - 500 μm for *Q. seminula* and 300 - 400 μm for *A. tepida*), the contribution of small juvenile individuals to sediment reworking has been neglected. Though our results non-ambiguously indicate that the contribution of benthic foraminifera to sediment reworking should not be neglected, these limitations warrant the need for further work to refine the relative contribution of foraminifera to intertidal sediment reworking rates. This would be achieved through the consideration of 1) the identification and further quantification of the species-specific traits likely impacting sediment reworking, 2) the role played by individuals of different sizes, and 3) the nature of the foraminiferal assemblages under scrutiny, including species richness and abundance.

Noticeably, *Quinqueloculina seminula* and *Ammonia tepida* specimens were consistently hidden in the sediment during our experiments, suggesting that the movement of these two species is not *sensu stricto* restricted to the sediment surface but may also have a vertical component as previously shown in *Q. impressa* [17]. These vertical movements are likely to modify sediment porosity and permeability [9], and affect a range of critical patterns and processes such as oxygen, pH and redox gradients as other infaunal invertebrates typically do. The horizontal and vertical movements of foraminifera are then likely to enhance the transport of sediment particles from the surface to the sedimentary column and the ventilation of cohesive intertidal sediments, as reported for deep-sea benthic foraminifera [23]. The resolution of this specific issue is, however, far beyond the objectives of the present study and further work is needed to disentangle the contribution of the movement of intertidal foraminifera to the facilitation of biogeochemical processes by the modifications of the physical properties of sediment induced by meiofauna [34].

In their work on, respectively, the annelid polychaete *Melinna palmata* and the bivalve *Abra ovata*, Massé *et al.* (2019) [35] and Maire *et al.* (2007) [36] measured $SSRR_i$ of these two macrofaunal species with a method closely similar to ours. It hence allowed for sound comparisons to assess to what extent the contribution to surface sediment fluxes of the two studied benthic foraminiferal species is important. The individual surface sediment reworking rates $SSRR_i$ of the two foraminiferal species considered in this study are one order of magnitude smaller than those reported for the polychaete *M. palmata* (1 to 5.5 $\text{cm}^2 \cdot \text{ind}^{-1} \cdot \text{day}^{-1}$; [35]), and the bivalve *A. ovata* (20 to 100 $\text{cm}^2 \cdot \text{ind}^{-1} \cdot \text{day}^{-1}$; [36]). However, considering the typical abundance of *M. palmata* (*i.e.* 277 $\text{ind} \cdot \text{m}^{-2}$, [37]) and *A. ovata* (*i.e.* 592 $\text{ind} \cdot \text{m}^{-2}$, [38]) in soft-sediment intertidal substrates, population-level surface sediment reworking rates $SSRR_p$ would respectively range from 277 to 1523 $\text{cm}^2 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$ from 11,840 and 59,200 $\text{cm}^2 \cdot \text{m}^{-2} \cdot \text{day}^{-1}$. For

A. ovata, these figures have the same order of magnitude as the population-level $SSRR_p$ estimated here for *Quinqueloculina seminula* and *Ammonia tepida* (Figure 2). Noticeably, however, the surface sediment reworking rates estimated for *M. palmata* are ca. 40-fold lower than the figures obtained for *Q. seminula* and *A. tepida* (Figure 2). We finally stress that because our experiments exclusively focused on the surface of the sediment, the figures reported in the present work for $SSRR_i$ and $SSRR_p$ are implicitly underestimating the contribution of benthic foraminifera to sediment reworking rates, which warrants both the importance of these minute organisms to overall sediment reworking rates and the need for further work.

5. Conclusions

Taken together, our result suggests that despite their minute size benthic foraminifera may play a significant role, though still largely overlooked, in intertidal mudflats sediment reworking. It is further stressed that because the fluxes of dissolved elements at the sediment-water interface [39] and bio-irrigation are known processes driven by meiofauna bioturbation [4], foraminifera may play an unsuspected role in the patterns and processes driving intertidal soft-sediment ecosystems. Further work is nevertheless needed to thoroughly assess 1) the relative contribution of a community of foraminifera compared to the one of macrobenthic organisms, and 2) the sediment reworking related to foraminiferal vertical movements. For instance, further assessment of the vertical mixing generated by foraminiferal motion behaviour should be an urgent question to tackle, since specimens were consistently shifting between “on the sediment surface” and “in sediment” positions in this study.

Acknowledgements

We would like to thank T. Bernard and D. Hurblain for their help in field sampling, and D. Langlet for his suggestions on an earlier version of the manuscript. This work is a contribution to the CPER research project CLIMIBIO. The authors thank the French Ministère de l'Enseignement Supérieur et de la Recherche, the Hauts de France Region and the European Funds for Regional Economical Development for their financial support for this project.
